**ABSTRACT.** We consider a generalization of replicator dynamics as a non-cooperative evolutionary game-theoretic model of a community of \( N \) agents. All agents update their individual mixed strategy profiles to increase their total payoff from the rest of the community. The properties of attractors in this dynamics are studied. Evidence is presented that under certain conditions the typical attractors of the system are corners of state space where each agent has specialized to a pure strategy, and/or the community exhibits diversity, i.e., all strategies are represented in the final states. The model suggests that new pure strategies whose payoff matrix elements satisfy suitable inequalities with respect to the existing ones can destabilize existing attractors if \( N \) is sufficiently large, and be regarded as innovations that enhance the diversity of the community.

**KEYWORDS:** Generalized replicator dynamics, evolutionary game theory, interacting agents, diversity, specialization.

1. Introduction

Replicator dynamics [Hofbauer and Sigmund, 1988; Weibull, 1995, Samuelson, 1996; Vega-Redondo, 1996; and references therein] is a standard model in evolutionary biology describing the dynamics of growth and decay of a number of species under selection pressure. Formally, consider $s$ species in an interactive environment, each genetically programmed to a particular behaviour with which it is identified. Tag the possible behaviours as 'strategies' belonging to the set $S = \{1, 2, \ldots, s\}$ in the sense of game theory. Let $A = [a_{ij}]$, $1 \leq i, j \leq s$, denote the payoff matrix with the following interpretation: the $i$-th species (playing strategy $i$) receives a payoff ($\approx$ contribution to its fitness) of $a_{ij}$ on interaction with species $j$. The rate of increase of the population $y_i(t)$ of species $i$ at time $t$ is assumed to be proportional to $y_i(t)$ and the birth rate minus the death rate. The latter is assumed constant, the former a constant modulated by an additive term equal to the average (current) payoff to $i$. Letting $z_i(t) = y_i(t)/(\sum_j y_j(t))$ denote the population share of $i$, simple algebra (see, e.g., Weibull, 1995) leads to replicator dynamics

$$
\dot{z}_i(t) = z_i(t)\left[\sum_j a_{ij}z_j(t) - \sum_{h,j} z_h(t)a_{hj}z_j(t)\right].
$$

(1.1)

The description makes the underlying biological formalism clear. A species is not allowed to change its strategy or 'genetic traits'. That is, 'ontogenetic adaptation' whereby individuals adapt to environment in their lifetime, is not permitted. Eq. (1.1) stands for 'phylogenetic adaptation' by the species as a whole in response to birth-death mechanism modulated by selection pressure. This makes eminent biological sense, because ontogenetic adaptation is not inherited, phylogenetic is.

More recently, however, the model has crossed the boundaries of biology. It has been taken up by economists as a model of economic learning. The motivation comes from the problem of equilibrium selection in game theory. Having concurred that Nash equilibrium is the most reasonable equilibrium concept for noncooperative games, one is confronted with the problem of choosing a 'natural' one from the overabundance thereof in a typical scenario. Many refinements were proposed, culminating in an elaborate theory of equilibrium selection [Harsanyi and Selten, 1988]. A recent departure from this trend has been to leave the static equilibrium framework in favour of dynamic models of disequilibrium and look for their asymptotic equilibria. Replicator dynamics and its variants have been a prominent front runner in this activity [see e.g. Mailath, 1992; Fudenberg and Levine, 1995]. The attractive feature of this model of evolutionary economics is that it builds in bounded rationality (agents are not perfect optimizers with perfect knowledge, infinite memory and computational ability, but make simple decisions based on immediate payoffs) and inertia (the adaptation takes place in incremental steps). Though originally meant to model 'phylogenetic learning' in biology, economists have successfully recovered it as a limiting case of models of individual, or ontogenetic learning [Borgers and Sarin, 1993; Ritzberger and Weibull, 1995] thus deriving 'macrobehaviour' from 'micromotives' [Schelling, 1978]. Prompted by this, there have been alternative models of evolutionary learning in economics [Young, 1993; Ellison and Fudenberg, 1995, for example].
Another motivation for considering dynamic models comes from the study of complex adaptive systems. A major question in this area is how do complex organizations emerge spontaneously in certain systems (e.g., chemical, biological and social systems). Implicit in the question is a notion of time evolution. One is interested the mechanisms whereby, starting from initial conditions where there is no organizational complexity, the system can end up in a state where an organizational character is discernible in which specific, nonrandom interaction between components of the system resulting in an overall coherence has emerged.

In this context generalizations of replicator dynamics have been considered in the literature (see Stadler, Fontana and Miller, 1993, and references therein).

In this paper we discuss another generalization [Borkar, Jain and Rangarajan, 1997], motivated by somewhat different concerns than earlier works. Mathematically, our model is simply a multipopulation variant of replicator dynamics [Weibull, 1994, Chapter 5]. Here, $N$ distinct populations, each with its strategy profile, evolve under selection pressure. Let $p^\alpha_i(t)$ denote the fraction of $\alpha$-th population that plays strategy $i$. The dynamics then is

$$
\dot{p}^\alpha_i(t) = p^\alpha_i(t) \left[ \sum_{\beta \neq \alpha} a_{ij} p^\beta_j(t) - \sum_{\beta \neq \alpha} \sum_{k \neq j} p^\beta_k(t) a_{kj} p^\beta_j(t) \right], \quad 1 \leq \alpha \leq N, \ 1 \leq i \leq s.
$$

(1.2)

Our interpretation, however, is different. We view Eq. (1.2) as a model of ontogenetic learning wherein the superscript $\alpha$, $1 \leq \alpha \leq N$, stands for $\alpha$-th agent, $p^\alpha_i(t)$ being the probability with which she plays strategy $i$ at time $t$. Thus $p^\alpha(t) \equiv (p^\alpha_1(t), p^\alpha_2(t), \ldots, p^\alpha_s(t))^T$ is her 'mixed strategy' at time $t$ and $\sum_{\beta \neq \alpha} \sum_{k \neq j} p^\beta_k(t) a_{kj} p^\beta_j(t)$ represents the payoff received by $\alpha$ from the rest of the community at time $t$. Eq. (1.2) then shows how agents adapt their strategies in response to payoffs received. The interpretation of the r.h.s. of Eq. (1.2) is that each agent increases the weight of those pure strategies that do better than her current (mixed) strategy in the environment of the current strategies of other agents, and decreases the weight of those that do worse, in proportion to the difference. The community as a whole evolves as all the individuals simultaneously make their updates. To emphasize this shift in paradigm from populations to individuals, we dub Eq. (1.2) 'generalized replicator dynamics' or GRD, rather than 'multipopulation replicator dynamics'. For contrast, Eq. (1.1) will be called 'pure replicator dynamics' or PRD.

Not only our interpretation, but the focus of our study is also different from that of Weibull [1994, Chapter 5]. Specifically, our primary aim will be to identify and analyse two key phenomena, which we dub 'specialization' and 'diversification'. By 'specialization', we refer to the situation in which every agent plays a pure strategy, i.e., for each $\alpha$, the probability vector $p^\alpha(t)$ is concentrated at a single point of the strategy space. In other words, while having the choice of choosing from the set of mixed strategies, thereby apportioning her resources (energy, time etc) on more than one activity, she chooses to put them all into a single activity. The kind of situations we are interested in are those in which this phenomenon goes hand in hand with another, that of 'diversification'. We say that diversification occurs in a community if for each possible strategy choice, there is at least one agent at any time who opts for it with positive probability.
That is, no available strategy is completely discarded by the community as a whole. Note that specialization is not a prerequisite for diversification. We do not require that agents in a diversified society use pure strategies in order for it to be considered as such. In fact, we do not even insist that they necessarily play distinct strategies. The society would still be deemed as being diversified if all of them played the same mixed strategy that puts positive probability mass on every strategy option. We do, however, look for situations where both specialization and diversification occur at the same time: while each agent puts all her eggs in one basket, no basket is left empty. Needless to say, we expect such behaviour only when the payoff matrix $A$ satisfies additional constraints. For example, if a strategy choice is strictly dominated by every other, one would indeed expect the society as a whole to opt out of it. Thus a significant part of the effort will be directed towards precisely nailing down what those conditions on $A$ might be.

The motivation for such an exercise is almost self-evident. We wish to capture qualitatively a phenomenon that recurs across a variety of evolutionary paradigms. If one looks at the evolution of human society from a primitive hunter-gatherer society to a modern town, one sees progressive specialization of essential tasks among individuals while no essential task is being completely discarded by the society as a whole. If one looks at the evolution of species on earth, one sees genetic strands diversifying to fill in specific ecological niches till their common ancestry is no longer obvious. In economics, the evolution from old manufacturing and trading patterns to a modern corporation is marked by extreme specialization and decentralization of tasks, while the corporation as a whole concurrently does a multitude of tasks that go into the meeting of its final objective.

This is just by the way of motivation. We delegate the issues of interpretation of the mathematical model to the discussion at the end of the paper and return to the mathematical formalism per se.

The quantity $z_i = (1/N) \sum_{a=1}^{N} p_{ia}$ is the population average of the probability that the strategy $i$ is being played by the entire collection of agents and can be interpreted as the relative weight of the $i$th strategy in the population. One might wonder whether this averaged out quantity satisfies the PRD equation when the individual $p_{ia}$ satisfy GRD. The answer is no even in the limit of large number of agents, as will be discussed later. Nevertheless, we find that in the large $N$ limit GRD contains a fair amount of “memory” about some of the PRD structures, in particular the interior equilibrium point of PRD, as we shall note later. The important point being made here, however, is that although our concept of diversification bears some similarity with concepts such as persistence and permanence for the PRD [Hofbauer and Sigmund, 1988], it is not subsumed or implied by these.

This paper is organized as follows: Section 2 reviews some known properties of PRD and GRD attractors, sets the notation and outlines the similarities and differences between PRD and GRD. This is followed by further results on the non-corner attractors of GRD. Section 3 identifies the conditions for the existence of maximal diversity in GRD, or preservation of all strategies in the population. Here we note the importance of large $N$ in promoting diversity in GRD. Explicit sufficient conditions for $s = 2$ and 3 are given, as well as partial results for higher $s$. Section 4 studies corner solutions in GRD which correspond to specialization.
in the community. Some theorems concerning the coexistence of specialization and diversity in the community are proved. Finally in section 5 we summarize our results from the previous sections, discuss their possible implications concerning specialization, diversity and innovation in economic communities, and mention some future directions.

2. NON-CORNER ATTRACTORS OF GRD

2.1. NON-CORNER EQUILIBRIA OF PRD

In this subsection we recall some well known facts about PRD (see Hofbauer and Sigmund, 1988, chapters 13, 19) that will be useful later and set some notation. Let $J$ denote the simplex of $s$-dimensional probability vectors, $J = \{x = (x_1, \ldots, x_s)^T \in \mathbb{R}^s | x_i \geq 0, \sum_{i=1}^s x_i = 1\}$. $J$ is the full configuration space of PRD dynamics, and is invariant under it, i.e., an $s$-dimensional probability vector remains so under evolution given by (1.1). Let $L$ denote a subset of $S$ with at most $s - 1$ elements. Then the set $F_L = \{x \in J | x_k = 0, k \in L\}$ is called a face of $J$. In particular if $L = \{k\}$, the corresponding face $F_{\{k\}}$ (denoted $F_k$ for brevity) is such that on this face the $k^{th}$ strategy is not represented in the population; the full diversity of available strategies is lost. All the faces $F_k$ together constitute the boundary of $J$. The relative boundary of each $F_k$ in turn is a union of the ‘subfaces’ $F_{kj} \equiv F_{\{k,j\}} = F_k \cap F_j, \partial F_k = \bigcup_{j \neq k} F_{kj}$, and so on. Finally, if $L$ has exactly $s - 1$ elements, say $L = S - \{i\}$, the corresponding face $F_L$ is a singleton, and will be called the ‘corner’ $C_i$ of $J$; only strategy $i$ survives in the population at $C_i$. All faces, subfaces, corners are invariant under PRD; if $x_k = 0$ at some time, it remains so thereafter. It follows that corners are trivially equilibrium points.

We are interested in the interior of $J$, i.e., $J^o = J - \bigcup_{k=1}^s F_k$. (The superscript $^o$ for a set will always denote its relative interior.) For trajectories that remain in $J^o$, all strategies are always present, since $0 < x_i < 1$ for all $i$. A point $x \in J^o$ that is a stationary point of (1.1) will be called an interior equilibrium point (IEP) of PRD. $x$ is an IEP of PRD only if the $s + 1$-dimensional vector $X = (x_0, x)$ satisfies

$$BX = E_0,$$

where $B$ is the $s + 1$-dimensional matrix

$$B = \begin{pmatrix}
0 & 1 & 1 & \cdots & 1 \\
-1 & & & & \\
-1 & & & & A \\
& & & & \\
& & & & \\
& & & & -1
\end{pmatrix}$$

and $E_0$ is the $s + 1$-dimensional unit vector $(1, 0, 0, \ldots, 0)^T$. (In (2.1) $X$ is represented as an $s + 1$-dimensional column vector). To see this, note that the $0^{th}$ component of (2.1) is just the normalization condition $\sum_{i=1}^s x_i = 1$, and the $i^{th}$ component is the equation $\sum_{j=1}^s a_{ij} x_j - x_0 = 0$. The latter statement means that the payoff for all strategies is $x_0$, independent of strategy, which, together
with the normalization condition is equivalent to the vanishing of the bracket on
the r.h.s. of (1.1). The solution to (2.1) is
\[ x_i = B^{-1} v_0 = u_i / \det B, \quad u_i \equiv \text{Cofactor of } B_{0i}, \]  
(2.3)
\[ x_0 = B^{-1} v_0 = \det A / \det B, \]  
(2.4)
provided \( \det B \neq 0 \). Note from the structure of \( B \) that
\[ \det B = \sum_{i=1}^{s} u_i. \]  
(2.5)
\( x_i \) being probabilities must be greater than or equal to zero, and for an interior
point, must be positive. This is guaranteed from (2.3) and (2.5) if

**A1**: \( u_i \neq 0 \quad \forall \ i, \) and all \( u_i \) have the same sign.

**A1** is a necessary and sufficient condition (on the payoff matrix \( A \)) for PRD to
have an isolated IEP, which, if it exists, is unique and given by (2.3). Sufficiency is
evident from the above. To see that **A1** is also necessary, observe that \( \det B = 0 \)
would imply that the solution of the linear equation (2.1) is not isolated, since
we could always add to \( X \) a vector proportional to a zero eigenvector of \( B \).

Dynamics within \( F_k \) can be studied using the submatrix \( A^{(k,k)} \) of the full payoff
matrix \( A \) (\( M^{(p,q)} \)) denotes the matrix obtained from a matrix \( M \) by deleting its
\( p^{th} \) row and \( q^{th} \) column; we will follow the convention for labelling the indices
that if the indices of \( M \) go over a set \( T \), then the row indices of \( M^{(p,q)} \) will
go over the set \( T - \{p\} \), and the column indices over the set \( T - \{q\} \). Denote
\( u_i^{(k)} \equiv \text{Cofactor of } (B^{(k,k)})_{0i}, i \in S - \{k\}, \) and define the following condition:

**A1** k: \( u_i^{(k)} \neq 0 \quad \forall \ i \neq k, \) and all \( u_i^{(k)} \) have the same sign.

It is clear from the above that if **A1** k is satisfied, then the relative interior of \( F_k \),
\( F^c_k = F_k - \partial F_k \) has an equilibrium point denoted \( x^{(k)} = (x_1^{(k)}, \ldots, x_s^{(k)}) \) with
\[ x_i^{(k)} = \frac{u_i^{(k)}}{\det B^{(k,k)}}, \quad i \neq k, \quad x_k^{(k)} = 0. \]  
(2.6)
with the payoff to all agents at this equilibrium point given by
\[ x_0^{(k)} = \frac{\det A^{(k,k)}}{\det B^{(k,k)}}. \]  
(2.7)

**A1** k is sufficient but not a necessary condition for \( F^c_k \) to have an equilibrium
point. An equilibrium point can also arise if \( u_k = 0 \) and all other \( u_i \) are non-
vanishing and have the same sign. However the latter equilibrium point is non-
generic, i.e., it happens only when the components of \( A \) satisfy an equation
\( (u_k = 0) \). This situation is structurally unstable: it can be destroyed by a small
perturbation of \( A \). Thus generically, \( F^c_k \) has at most one equilibrium point (one,
given by (2.6) if **A1** k holds, and none if it is violated). The generic equilibrium
point is characterized by equal payoffs to all strategies except \( k \), which is just
ignored, and the non-generic one by the fact that even the \( k^{th} \) strategy receives
the same payoff as all other strategies. An analogous situation holds for the equilibrium points in the interior of subfaces \( F_k \), etc.

For all trajectories that do not converge to the boundary of \( J \), the barycentre of every invariant probability measure supported in the interior is the IEP of PRD. To see this, define \( \bar{z}_i = \lim_{T \to \infty} \frac{1}{T} \int_0^T dt \, x_i(t) \) and \( c = \lim_{T \to \infty} \frac{1}{T} \int_0^T dt \, \sum_{k,j=1}^N k_j \, x_k(t) a_{ij} \, x_j(t) \) along some common convergent subsequence. From (1.1) it follows that \( \bar{z}_i / x_i = (A\bar{z})_i - x_i^T A \). Integrating w.r.t. \( t \) from zero to \( T \), dividing by \( T \) and taking the limit along appropriate subsequence gives

\[
\lim_{T \to \infty} \frac{1}{T} \left[ \ln x_i(T) - \ln x_i(0) \right] = (A\bar{z})_i - c.
\]

(2.8)

Since by assumption \( x_i \) is bounded away from zero, the l.h.s. vanishes. Therefore \( (A\bar{z})_i \) is independent of \( i \), which, together with the normalization condition on \( \bar{z} \) means that \( \bar{z}_i \) must coincide with the IEP (2.3). Similarly, for generic \( A \), for all trajectories in \( F_k \) that do not converge to its relative boundary, the barycentre of every invariant probability measure supported in \( F_k \) is given by (2.6).

In the remainder of this section we will show that above results for PRD have appropriate generalizations in GRD, and also discuss some departures.

2.2. GRD PRELIMINARIES

2.2.1. NOTATION, DEFINITION OF SPECIALIZATION AND DIVERSITY

The configuration space of GRD will be denoted \( J^N = \Pi_{\alpha=1}^N J^{(\alpha)} \) where \( J^{(\alpha)} \) is a copy of \( J \) for the \( \alpha \)-th agent. A point of \( J^N \) will be denoted \( p = (p^{(1)}, p^{(2)}, \ldots, p^{(N)}) \), where \( p^{(\alpha)} = (p^{(\alpha)}_1, p^{(\alpha)}_2, \ldots, p^{(\alpha)}_s) \in J^{(\alpha)} \). For many purposes it will be convenient to think of \( J^N \) to be embedded in \( R^{N_s} = \Pi_{\alpha=1}^N R^{s(\alpha)} \) where \( R^{s(\alpha)} \) is a copy of \( R^s \) for the \( \alpha \)-th agent and \( J^{(\alpha)} \subset R^{s(\alpha)} \). Then we can write \( p = (p_1, p_2, \ldots, p_N) \equiv (p_\alpha) \), \( p_\alpha \geq 0 \). \( \alpha \) runs over the index set \( \alpha N = \{1, 2, \ldots, Ns\} = \cup_{\alpha=1}^N S(\alpha) \), where the set \( S(\alpha) = \{(\alpha-1)s+1, (\alpha-1)s+2, \ldots, \alpha s\} \) will be called the \( \alpha \)-th block (of indices). \( e_\alpha \) will denote the unit vectors along the axes of \( R^{s(\alpha)} \), the \( \alpha \)-th component of \( e = (e^b)_\alpha = e^b_\alpha \). Thus \( J^N = \{ p \in R^{N_s} \mid p_\alpha \geq 0 \}, \sum_{\alpha S(\alpha)} p_\alpha = 1 \forall \alpha = 1, 2, \ldots, N \}, \) and \( J^{(\alpha)} = \{ p \in R^{s(\alpha)} \mid p_\alpha \geq 0 \forall \alpha, p_\alpha = 0, \beta \notin S(\alpha), \sum_{\beta \notin S(\alpha)} p_\beta = 1 \}. \) The notation \( b = (\alpha, i) \) will denote that \( b \) is the \( i \)-th element in the \( \alpha \)-th block.

We now define a face of \( J^N \). Let \( L \) be any subset of \( \alpha N \) such that it contains at most \( s - 1 \) indices from each block. Then the set \( F_L = \{ p \in J^N \mid p_\alpha = 0, b \in L \} \) will be called a face of \( J^N \). A face \( F_L \) will be called a 'surface' of \( F_L \) if \( L \) is a proper subset of \( L' \). Clearly if \( L = \emptyset, F_L = J^N \). If \( L \) is of order \( N(s - 1), \) i.e., it has exactly \( s - 1 \) elements from each block, then \( F_L \) is a singleton and will be called a corner of \( J^N \). If for some \( \alpha, p^{(\alpha)} \) goes to a corner \( C_\alpha \) of \( J^{(\alpha)} \), this of course means that the agent \( \alpha \) has opted for the pure strategy \( i \), and we say that \( \alpha \) has 'specialized' in strategy \( i \). At a corner of \( J^N \), every agent has specialized to some strategy or the other and we say that the community is 'fully specialized'. \( J^N \) is invariant under GRD, as the \( L^1 \) norm and positivity of every \( p^{(\alpha)} \) is preserved under (1.2). Every face of \( J^N \) is invariant under GRD, as \( p^{(\alpha)}_b(t) = 0 \forall t \) if it is zero for some \( t \). Therefore corners are trivially equilibrium points. This does not, however, mean that they are stable. If corners of \( J^N \) are the only asymptotically stable attractors of the dynamics defined by (1.2),
we will say that the latter exhibits specialization. For then, the community will always end up being fully specialized, starting from (a small perturbation of) any initial condition.

If \( L = \{ k, s+k, 2s+k, \ldots, (N-1)s+k \} \) for some \( k \in S \) the corresponding face \( F_L \) is one where every agent has opted out of the \( k \)th strategy. Such faces will be particularly important for us and we will denote them as \( F_k \). They are analogues of the \( F_h \) defined in the previous subsection, where a particular strategy \( k \) becomes extinct from the population. At a face \( F_k \) the full diversity of strategies is lost. Conversely the complement of the set \( \bigcup_{k=1}^{N} F_k \) in \( J^N \) corresponds to the situation where every strategy is represented in the community and we denote this set by \( J^N_D \), with the subscript \( D \) denoting the fact that the full ‘diversity’ of strategies is maintained. Note that we use the word ‘diversity’ not to signify the variation between individual agents, but as a measure of the size of set of strategies being pursued. Indeed we can have no variation but full diversity if all agents pursue the same mixed strategy: for all \( \alpha, p^\alpha = c \in J^N \). When \( p^\alpha \) is independent of \( \alpha \), the community is completely ‘homogeneous’ since all agents are doing the same thing. Also we remark that the community can be fully specialized and diversified at the same time: each agent chooses a pure strategy and every strategy is chosen by some agent or the other.

In order to maintain the full diversity of strategies in the society, no strategy \( k \) should be dynamically opted out of by all agents. That is, no trajectory that starts in the interior of \( J^N \) should end up in any of the faces \( F_k \). Better still, any trajectory in a face \( F_k \) should become unstable with respect perturbations that take it into the interior of \( J^N \). The basic idea is that while under the dynamics (1.2) a trajectory in \( F_k \) will always remain in it, in practice in a real society, agents will always be subject to influences that draw their attention to strategies that do not exist in the population, but are valid strategies within the capabilities of the agents. Such influences can be thought of as perturbing the society away from the face \( F_k \). If \( F_k \) is unstable to small perturbations, then this perturbation will grow. If all faces \( F_k \) are unstable, no strategy can in practice become extinct from the population. We will say that the dynamics (1.2) exhibits diversity if every trajectory in each of the faces \( F_k \) of \( J^N \) becomes unstable at some time or the other with respect to small perturbations that deform it away from \( F_k \). This notion of diversity is analogous to the notions of permanence [Schuster, Sigmund and Wolff, 1979], persistence [Butler, Freedman and Waltman, 1986, and references therein], etc., which have been defined in PRD to study the extinction of strategies (see Hofbauer and Sigmund, 1988 for definitions).

It is evident that the boundary of \( J^N \) is given by the union of all faces in which exactly one of the \( p_\ beta's is zero, \( \partial J^N = \bigcup_{\alpha=1}^{N} F_{\{\alpha}\} \). In general the relative boundary of \( F_L \) is given by \( \partial F_L = \bigcup_{k \in L} \{ p \in F_L | p_k = 0 \} \), where \( L \) is the complement of \( L \) in \( S_N \). The relative interior of a face \( F_L \) is defined as \( \overset{\circ} F_L = F_L - \partial F_L \). Note that unlike in PRD here the boundary of \( J^N \) not the same as \( \bigcup_{k=1}^{N} F_k \); the latter is a subset of \( \partial J^N \). Similarly \( \bigcup_{j \neq k} F_{kj} \) (where \( F_{kj} = F_k \cap F_j \)) is a subset of the boundary of \( F_k \).
In general, \( p \in J^N \) is an equilibrium point for Eq. (1.2) if for every \( b = (\alpha, i) \in S_N \), either \( p_0 = 0 \), or,
\[
\sum_{\beta \neq \alpha} \sum_{j} a_{ij} p^\beta_j = \sum_{\beta \neq \alpha} \sum_{k,j} p^\alpha_k a_{kj} p^\beta_j.
\] (2.9)

Note that the right hand side of the above equation is independent of \( i \). Combining this with the fact that \((p^\alpha_1, p^\alpha_2, \ldots, p^\alpha_N)\) is a probability vector, one can replace Eq. (2.9) by: \(\sum_{\beta \neq \alpha} \sum_{j} a_{ij} p^\beta_j\) is the same for all \( i \) for which \( p^\alpha_i > 0 \). At an equilibrium point an agent receives the same payoff for all the pure strategies she has not opted out of.

2.2.2. Review of Some Known Results for GRD

We now recall some known facts about equilibria (and other attractors) of GRD from Chapter 5, Weibull (1995). (See this reference for relevant definitions.)

**Theorem 2.1** If strategy \( i \) is either dominated or iteratively dominated, \( p^\alpha_i(t) \rightarrow 0 \ \forall \alpha \).

**Theorem 2.2** All interior equilibria and Liapunov stable equilibria of Eq. (1.2) are Nash equilibria. Also, if an interior trajectory of Eq. (1.2) converges to a point, the same must be a Nash equilibrium.

**Theorem 2.3** Any compact set in the relative interior of a face cannot be asymptotically stable.

Note that strict Nash equilibria are perforce pure strategy Nash equilibria and therefore correspond to corner solutions which we identify as 'specialization' in behavioural sense.

2.2.3. Differences between PRD and GRD

Note that (1.1) is of the form \( \dot{x}_i = x_i(f_i(x) - \bar{f}(x)) \), with \( f_i(x) = \sum_{j \in S} a_{ij} x_j \) and \( \bar{f}(x) = x^T f(x) \). The GRD equation (1.2) does not have quite this form. Let \( \tilde{A} \) denote the \( Ns \times Ns \) matrix given by
\[
\begin{pmatrix}
0 & A & A & \cdots & A \\
A & 0 & A & \cdots & A \\
\vdots & \vdots & \vdots & \ddots & \vdots \\
\vdots & \vdots & \vdots & \ddots & \vdots \\
A & A & \cdots & \cdots & 0
\end{pmatrix}
\] (2.10)

where \( 0 \) is a \( s \times s \) zero matrix. Then indeed (1.2) can be written as \( \dot{p}_b = p_b(f_b(p) - \bar{f}(p)) \), with \( f_b(p) = \sum_{c \in S_N} A_{bc} p_c \). But now \( \bar{f}(p) \) is no longer given by \( p^T f(p) \), but by \( p^{(\alpha)}^T f(p) \), where \( p^{(\alpha)} \) is the projection of \( p \) onto the block \( \alpha \), to which \( b \) belongs \((p^{(\alpha)}_b) = p_c \) if \( c \) is in the same block as \( b \) and zero otherwise.

Second, note that in GRD every agent plays against other agents only, not against herself. That is, if agent \( \alpha \) were to play pure strategy \( i \), her payoff,
\[ \sum_{\beta \neq \alpha} \sum_{j} a_{ij} p_j^\beta, \] excludes the term \( \beta = \alpha \). We will see later that this fact is crucial for the coexistence of specialization and diversity.

If the initial point of a trajectory in GRD is homogeneous, the trajectory remains homogeneous for all time, and evolves according to (1.1) except that the time is speeded up by a factor of \( N - 1 \). This is evident upon substituting \( p_j^\alpha = p_j^\beta \) in (1.2). Thus in the 'homogenous sector', GRD is the same as PRD.

The sum \( \bar{x}_i \equiv (1/N) \sum_{\alpha=1}^{N} p_i^\alpha \) equals the average probability that strategy \( i \) is being played in the entire community, and is therefore the analogue of \( x_i \) in PRD. We can ask how \( \bar{x}_i \) evolves in GRD. It is easy to see that

\[ \dot{x}_i = N \left[ \bar{x}_i \sum_{j} a_{ij} \bar{x}_j - \sum_{k,j} x_{ik} a_{kj} \bar{x}_j - \frac{1}{N} \sum_{j} x_{ij} a_{ij} + \frac{1}{N} \sum_{k,j} x_{ik} a_{kj} \right], \tag{2.11} \]

where \( x_{ik} \equiv \frac{1}{N} \sum_{\alpha} p_i^\alpha p_k^\alpha \) and \( x_{ikj} \equiv \frac{1}{N} \sum_{\alpha} p_i^\alpha p_k^\beta p_j^\alpha \). The r.h.s. of (2.11) is not proportional to the r.h.s. of (1.1), except for homogeneous trajectories in which case \( x_{ik} = \bar{x}_i \bar{x}_k, x_{ikj} = \bar{x}_i \bar{x}_k \bar{x}_j \). Thus in general \( \bar{x}_i \) does not follow the PRD. One might have hoped that when the number of agents \( N \) is large \( \bar{x}_i \) follows PRD, but even that is not the case due to variation among the agents. For example, consider an asymptotically stable equilibrium point, which we are assured by theorem 2.3 must be a corner, in which the number of agents pursuing the pure strategy \( i \) is given by \( n_i \). Then the difference between \( x_{ik} \) and \( \bar{x}_i \bar{x}_k \) is \( n_i (N \delta_{ik} - n_k) / N^2 \), which can be comparable to the former two even for large \( N \) (except for homogeneous corners).

One of our main results in this paper is that even though variation among agents, which is generic in GRD causes the evolution of \( \bar{x}_i \) to be different from PRD, under suitable conditions for \( A \) and sufficiently large \( N \), \( \bar{x}_i \) nevertheless converges to the IEP of PRD given by (2.3).

### 2.3. Some results on non-corner attractors of GRD

We shall be interested in 'generic' behaviour, i.e., behaviour that holds true for \( A \) in an open and dense set of \( \mathbb{R}^{+\times \times} \). Thus all claims made in this subsection are for generic \( A \), not necessarily for all \( A \). First, we prove that

**Theorem 2.4** There exists at most one isolated equilibrium in the interior of \( J^N \). It exists if and only if \( A1 \) is satisfied and then it is homogeneous (all agents pursue the same mixed strategy), and coincides with the IEP of PRD, \( p_i^\alpha = x_i \forall \alpha, i \) (Borkar, Jain and Rangarajan, 1998).

**Proof:** Let \( p \in J^{N^\alpha} \) be an equilibrium point. By definition no \( p_k \) is zero in the interior of \( J^N \). Therefore (2.9) holds for all \( \alpha, i \). Define \( \bar{x}^\alpha_i \equiv \sum_{\beta \neq \alpha} \sum_{i,j} p_i^\alpha a_{ij} p_j^\beta \), and \( v_i^\alpha \equiv \sum_{\beta \neq \alpha} p_i^\beta \). Then \( \bar{x}^\alpha_i = -1 \forall \alpha \), and (2.9) can be written as

\[ BX^\alpha = (N - 1)E_0 \] for every \( \alpha \), where \( X^\alpha \equiv \{ \bar{x}^\alpha_i, v_1^\alpha, v_2^\alpha, \ldots, v_N^\alpha \}^T \). This equation is the same as (2.1) except for the factor of \( N - 1 \) on the right. Therefore it has a solution if and only if \( A1 \) holds. The solution is unique and given by

\[ v_i^\alpha = (N - 1) \bar{x}_i \forall \alpha. \] Since \( p_i^\alpha - p_i^\beta = v_i^\alpha - v_i^\beta = 0 \), it follows that the equilibrium point is homogeneous and given by \( p_i^\alpha = \bar{x}_i \). \( \square \)
Corollary 2.1 For generic $A$ there exists at most one equilibrium point of GRD in the interior of face $F_k$. This generic equilibrium point exists if $A1_k$ is satisfied and then it is homogeneous and is given by $p_i^o = x_i^{(k)} \forall \alpha, i$, where the r.h.s. is given by (2.6), and the payoff to each agent at this point is $(N-1)x_i^{(k)}$, with $x_i^{(k)}$ given by (2.7). If $A1_k$ is violated, there is generically no equilibrium point in $F_k$.

This follows from arguments similar to those discussed above for the faces $F_k$ of PRD. □

In fact, one can show that generically, there is at most one equilibrium of Eq. (1.2) in the relative interior of any face of $J^N$. Note that (2.9) can be written as

$$(\dot{A}p)_b = p^{(a_0)}_b \dot{A}p,$$  

(2.12)

where we use the notation $b = (\alpha_b, i_b)$. The r.h.s. depends only on $\alpha_b$ and not on $i_b$.

Let us consider an equilibrium point in the interior of the face $F_L$. By definition, if $p \in F_L$, $p_b = 0$ except for $b \in L^C \equiv H$. Let $H$ have $m$ elements. Then $m \leq N$ because $H = L^C$ implies that $H$ contains at least one element from each block. If we partition $H$ as $H = \bigcup_{a=1}^N H_a$, where $H_a$ is the intersection of $H$ with the $\alpha^{th}$ block, then $H_a \neq \emptyset \forall \alpha$. For the $m$ components of $p$ which are non-zero, the condition for equilibrium is (2.9) or (2.12). Therefore $p$ is an equilibrium point in $F^C_L$ if $(\dot{A}p)_b$ is independent of $i_b \forall b \in H$ (or equivalently, if $(\dot{A}p)_b = (\dot{A}p)_{b'}$ whenever $b$ and $b'$ are in the same block and are elements of $H$).

This condition can be interpreted geometrically as follows: Define $\dot{E}$ as the subspace of $R^{N^s}$ consisting of all vectors $r = \sum_{b=1}^{N^s} r_b \delta^b$ such that $r_b = r_{b'}$ whenever $b$ and $b'$ are in the same block and are elements of $H$. There are $m - N$ conditions on the components of $r$, hence $\dot{E}$ is $N^s - (m - N) = N(s + 1) - m$ dimensional. Define $D = \{q \in R^{N^s} | q_b = \sum_d \hat{A}_{bd} p_d, p \in F_L\}$. It is evident from the conditions mentioned above that if $p \in F^C_L$ is an equilibrium point of GRD then $q = \dot{A}p$ belongs to $\dot{E}$, i.e., $\dot{E} \cap D^o \neq \emptyset$, and vice versa.

Note that since the only nonzero components $p_d$ appearing in the definition of $D$ are those for which $d \in H$, only the corresponding columns $\hat{A}_d$ of $\hat{A}$ appear. Then, interpreting each column $\hat{A}_d$ of $\hat{A}$ as a point in $R^{N^s}$, $D$ is the compact convex subset of the polytope generated by the $m$ points $N\hat{A}_d$, $d \in H$. $D$ is contained in an affine space of dimension at most $m - N$. To see this let $\bar{D}$ denote the smallest affine space (i.e., translate of a subspace of $R^{N^s}$) that contains $D$. Since the $p_d$'s in the definition of $D$ must add to 1 when summed over $d$ belonging to any block, and there are $N$ such conditions, the dimension of $F_L$ is $m - N$, and that of $\bar{D}$ is $m - N$ if the $\hat{A}_d$'s are linearly independent, and less if not.

Theorem 2.5 For generic $A$, there is at most one equilibrium of GRD per face of $J^N$.

Proof: The proof is based on the correspondence discussed above between the equilibrium points in the interior of the face $F_L$ and the convex set $\dot{E} \cap D^o$. Without loss of generality we ignore the point faces (corners). Suppose $\dot{E} \cap D^o$ has dimension one or more. We must show that this situation is structurally
unstable under a perturbation of $A$. Clearly, $m > N$, or else $D$ itself is a singleton. In particular, at least one $H_\alpha$, say $H_{\alpha_0}$, has more than one element. If $\bar{E} \cap D^\circ$ has dimension one or more, it contains a line segment. Every point on a line segment is a convex combination of its endpoints. Thus there are two or more $\bar{A}_d$'s whose uncountably many convex combinations lie in $\bar{E}$. From our definition of $\bar{E}$, all of them must have the property that their components corresponding to indices in $H_{\alpha_0}$ are equal. It is clear that, if for two distinct vectors, infinitely many convex combinations of their prescribed components are equal to one another, the vectors themselves must have this property. Then the $\bar{A}_d$'s in question must also have this property. But this property is destroyed by a suitable perturbation of $A$.

Now suppose $\bar{E} \cap D = \emptyset$. Since $\bar{E}$, $D$ are closed convex and $D$ compact, this is equivalent to a nonzero distance between the two and therefore stable under a small perturbation of $A$, hence of $D$. Let $\bar{E} \cap D^\circ = \{y\}$. Since $D$, $\bar{E}$ have at most complementary dimensions in $\mathbb{R}^N$, this can happen only when $\bar{E}$, $D$ are transversal at $y$, a situation stable under a small perturbation of $A$, hence of $D$. Finally, if $\bar{E} \cap D = \{y\}$ with $y$ in the relative boundary of $D$, a small perturbation of $A$ will lead to either a similar situation, or to one of the scenarios considered above. The claim follows. \hfill \Box

In the remainder of this section, we assume $A$ to be such that the above conclusions hold. The next two results relate general (non point) limit sets of GRD with its equilibria. Recall that a trajectory $x(\cdot)$ in a Euclidean space is said to converge to a point $\bar{x}$ (or a set $C$) in Cesaro sense if $\frac{1}{t} \int_0^t x(r)dr \to \bar{x}$ (resp. $C$) as $t \to \infty$. For the remainder of this subsection, by convergence we will mean convergence in the Cesaro sense. This is to take care of some pathological behaviour that can occur.

As before let $F_L$ be a face whose relative interior is $F_L^\circ = \{p \in J^N | p_b > 0 \text{ iff } b \in L\}$. Define $H$, $D$, $\bar{E}$ as before.

**Theorem 2.6** Any trajectory $p(\cdot)$ of GRD in $F_L^\circ$ converges either to its relative boundary or to an equilibrium point in $F_L^\circ$.

**Proof** Suppose it does not converge to the relative boundary of $F_L$. Then there exist $t_k \uparrow \infty$ such that $\{p_b(t_k)\}$ remains bounded away from zero for each $b \in H$. Define $\bar{p}(t) \in H$ by

$$\bar{p}_b(t) = \frac{1}{t} \int_0^t p_b(r)dr \quad \forall \ b, t.$$  \hspace{1cm} (2.13)

By dropping to an appropriate subsequence, let

$$\bar{p}(t_k) \to \bar{p}^* \in F_L$$ \hspace{1cm} (2.14)

and

$$\frac{1}{t_k} \int_0^{t_k} p^{(\alpha)}(t)^T \bar{A} p(t) dt \to e^{\alpha} \in R$$ \hspace{1cm} (2.15)

where $p^{(\alpha)}$ is the projection of $p$ onto $J^\alpha$. Rewrite GRD as

$$\bar{p}_b(t)/p_b(t) = (\bar{A} p(t))_b - p^{(\alpha)}(t)^T \bar{A} p(t), \quad b \in H.$$ \hspace{1cm} (2.16)
Integrating, we have, for \( b \in H \),
\[
\frac{\ln p_b(t_k)}{t_k} - \frac{\ln p_b(0)}{t_k} = \int_0^{t_k} [(\tilde{A}p(r))_b - p^{(\alpha)}(r)^T \tilde{A}p(r)] dr.
\] (2.17)

Let \( k \to \infty \) to obtain
\[
(\tilde{A}p^*)_b = c^{\alpha}, \quad b \in H.
\] (2.18)

Now \( \tilde{A}p^* \in D \) while an \( N \)-vector whose \( b^{th} \) element is \( c^{\alpha} \), independent of \( i_b \) if \( b \in H \), zero otherwise, is clearly in \( \tilde{E} \). By the preceding theorem and our choice of \( A \) (generic), Eq. (2.18) uniquely specifies \( p^* \) as the unique GRD equilibrium in \( F_\infty^0 \). Now, \( t \to p(t) \) is continuous and hence converges to a compact connected set \( C \) in \( F_L \). The foregoing implies that \( C \cap F_\infty^0 = p^* \). By connectedness of \( C \), \( C = \{p^*\} \). This completes the proof. \( \square \)

We now give an alternative interpretation to this result. GRD defines a compact flow in \( J^N \) and has a nonempty compact convex subset of invariant probability measures whose extreme points correspond to the ergodic measures [Sell, 1971, Ch. IX]. Recall that the barycentre of a probability measure on a Euclidean space \( \mathbb{R}^n \) is the point \( x_0 \in \mathbb{R}^n \) for which \( f(x_0) = \int f d\mu \) for all affine (i.e., linear plus constant) \( f \). The above theorem can then be rephrased as

**Theorem 2.6'** Every invariant probability measure of GRD supported in \( F_L \), whose support intersects \( F_k^0 \), has a common barycentre given by the unique GRD equilibrium in \( F_\infty^0 \). \( \square \)

**Corollary 2.2** If \( A1 \) holds, all trajectories that do not converge to the boundary of \( J^N \) converge (in the Cesaro sense) to \( p_i^0 = x_i \lim \alpha_i \) with \( x_i \) given by (2.3). Also if \( A1_k \) holds, all trajectories in the face \( F_k \) that do not converge to its boundary converge to \( p_i^a = x_i^{(k)} \lim \alpha_i \), with \( x_i^{(k)} \) given by (2.6).

This follows upon using theorem 2.4 and corollary 2.1 in theorem 2.6'. \( \square \)

We also have:

**Corollary 2.3** If \( F_\infty^0 \) does not have any GRD equilibria, every trajectory of GRD therein must converge to the relative boundary of \( F_L \). \( \square \)

Thus the typical picture is: each non-point face has zero or one GRD equilibrium. In the former case, all trajectories initiated in the face must converge to its relative boundary (in the Cesaro sense). In the latter, the equilibrium is not asymptotically stable, though it can still be Liapunov stable. Any trajectory in the interior of the face must converge either to this equilibrium or to the relative boundary of the face. The former allows, e.g., a 'centre', i.e., a family of periodic orbits around an equilibrium. If the condition \( A1 \) holds, there is a unique equilibrium point in the interior of \( J^N \) which is homogeneous and coincides with the IEP of PRD for every agent. For every trajectory in \( J^N \) that does not converge to its boundary, the time average of the trajectory (over long times) converges to this point. A similar result holds for the face \( F_k \) (at which the \( k^{th} \) strategy becomes extinct) if condition \( A1_k \) is satisfied.

Finally, we discuss the presence of 'heteroclinic cycles' in our dynamics. A heteroclinic cycle for an ordinary differential equation consists of finitely many
equilibria, each one connected to the next by a trajectory of the o.d.e which has the former as its $\alpha$-limit point and the latter as its $\omega$-limit point. The following two theorems are useful in making the connection between heteroclinic cycles and GRD dynamics:

**Theorem 2.7** For generic payoff matrices, every asymptotically stable attractor for the GRD contains one or more corner equilibria.

**Proof** Let $C$ be an asymptotically stable attractor of the GRD which is not an equilibrium point. Then $C$ is a compact subset of the state space. Let $F$ be an (open) face and $G$ its boundary such that $F \cup G$ contains $C$. Let $F$ be $k$-dimensional. Then $G$ is a union of faces of dimension $k - 1$ or less. $C$ cannot be in the relative interior of $F$, because then it cannot be asymptotically stable. Thus $C' = C \cap G$ is nonempty. $G$ itself is invariant for the o.d.e. If $C'$ is not asymptotically stable for the flow restricted to $G$, nor will be $C$. Thus $C'$ is asymptotically stable for the flow restricted to $G$ and by the same argument as before, it cannot be in the union of relative interiors of $(k - 1)$-dimensional faces of $G$. That is, it has a nonempty intersection with the complement thereof in $G$, which is a union of faces of dimension $k - 2$ and lower. This argument can be repeated to conclude that $C$ must contain some corner equilibria. \[\square\]

**Theorem 2.8** If an attractor contains only finitely many $\omega$- and $\alpha$-limit points (which then must be equilibria), it is a heteroclinic cycle.

This is same as Corollary 1.4, pp. 146 in [Benaim and Hirsch, 1996].

The two theorems together strongly suggest that we can expect heteroclinic cycles in GRD. In fact, in our numerical simulations, in the few cases that did not lead to convergence to corner equilibria, the behaviour was strongly suggestive of heteroclinic cycles as attractors. That is, the trajectory spent ever increasing amounts of times near a succession of corner equilibria, moving relatively quickly, when it did, between two. We are tempted to conjecture that convergence to corner equilibria or heteroclinic cycles containing them is generic. We remark that long periods of static punctuated by rapid change have also been noted in other evolutionary contexts.

### 3. CONDITIONS FOR DIVERSITY IN GRD

As defined in section II B, the property of diversity has to do with the instability of trajectories in $F_k$ with respect to perturbations away from $F_k$. Consider a generic point $p \in F_k$. By definition $p^\alpha_k = 0 \forall \alpha$, or $p^\beta_k = 0 \forall \beta \in \{k, s + k, 2s + k, \ldots, (N - 1)s + k\}$. Now consider a perturbation of this point that takes it away from $F_k$. This is achieved by making $x^\alpha \equiv p^\alpha_k$ nonzero. Consider the dynamics of the $N$-tuple $x = (x^1, \ldots, x^N)$ under GRD ($x$ is just the collection of the $k^{th}$ components of the $p^\alpha_k$), treating the other components of $p$ (which determine the location on $F_k$) as fixed parameters. The linearized $N \times N$ Jacobian matrix of this dynamics evaluated turns out to be diagonal and therefore its eigenvalues at $x = 0$ will determine the stability of the point $p \in F_k$. 

with respect to perturbations away from \( F_k \). (Strictly speaking, we are not justified in treating the other components of \( p \) as fixed parameters because every \( p^\alpha \) is normalized to unity and a nonzero \( x^\alpha \) implies that the other components of \( p^\alpha \) must also change. However, we will show later that this does not affect the Jacobian matrix.)

We use the notation that the capital Roman indices \( I, J, K, \text{ etc.} \) go over the set \( S - \{ k \} \). Then \( \sum_{j=1}^J a_{ij}^\alpha p_j^\beta = \sum_j a_{ij}^\alpha p_j^\beta + a_{ik} x^\beta \). Thus (1.2) gives

\[
\dot{x}^\alpha = f^\alpha(x; p) = x^\alpha \left( \sum_{\beta \neq \alpha} \sum_J a_{\beta j} p_j^\beta - \sum_{\beta \neq \alpha} \sum_{K,J} p_K^\alpha a_{KJ} p_j^\beta \right) + \text{terms linear and quadratic in } x^\alpha. \tag{3.1}
\]

Therefore the above mentioned jacobian matrix is

\[
J_{\alpha \gamma}(p) \equiv \left. \frac{\partial f^\alpha(x; p)}{\partial x^\gamma} \right|_{x=0} = \delta_{\alpha, \gamma} \left( \sum_{\beta \neq \alpha} \sum_J a_{\beta j} p_j^\beta - \sum_{\beta \neq \alpha} \sum_{K,J} p_K^\alpha a_{KJ} p_j^\beta \right). \tag{3.2}
\]

Since this is already diagonal, its eigenvalues as a function of the point \( p \) in the face \( F_k \) are

\[
\lambda_\alpha(p) = \sum_{\beta \neq \alpha} \sum_J a_{\beta j} p_j^\beta - \sum_{\beta \neq \alpha} \sum_{K,J} p_K^\alpha a_{KJ} p_j^\beta. \tag{3.3}
\]

Now we discuss the justification of treating \( x^\alpha \)'s as variables independent of \( p \). Note that at \( x = 0 \) the terms linear and quadratic in \( x \) inside the \( [ \] \) in \( f^\alpha(x; p) \) do not contribute. In general we could consider stability along any trajectory in \( J^M \) that is transversal to \( F_k \) at \( p \). For small \( x \), such a trajectory could be parametrized as \( p_K^\alpha(t) = C_{K\alpha}^0 + C^0_{\alpha} t \), \( x^\alpha(t) = C^\alpha_\alpha t \), where the \( C_\alpha^0 \)'s are constants that can be chosen suitably to preserve the normalization of \( p^\alpha \). Effectively, this means that for small \( x \), we can replace \( p^\alpha \) in \( f(x; p) \) by a linear function of \( x^\alpha \). This makes no contribution to the \( [ \] \), and hence the jacobian, at \( x = 0 \). Thus the stability along any trajectory will be governed by the \( \lambda_\alpha \) given by (3.3). Thus we have proved

**Lemma 3.1** A trajectory in \( F_k \) passing through \( p \) is unstable with respect to perturbations away from \( F_k \) at \( p \) if the largest of the \( \lambda_\alpha(p) \) given by (3.3), \( \alpha = 1, 2, \ldots, N \), is greater than zero at \( p \). □

\( \lambda_\alpha \) has a simple economic interpretation. The first term is the payoff to agent \( \alpha \) if she were to pursue the pure strategy \( k \) at \( p \), other agents remaining at \( p \). The second term is the payoff she is actually getting at \( p \), where she is playing \( p^\alpha \). The instability of \( F_k \) if \( \lambda_\alpha > 0 \) is just the statement that movement towards the \( k^{th} \) strategy yields a better payoff to agent \( \alpha \) than her current strategy.

### 3.0.1. Stability of interior trajectories of \( F_k \)

We now wish to consider the long time average of \( \lambda_\alpha(p) \) as \( p \) moves around in \( F_k \), i.e., the quantity \( \bar{\lambda}_\alpha = \frac{1}{T} \int_0^T dt \lambda_\alpha(p(t)) \), for trajectories in \( F_k \) that do not converge to its relative boundary. Recall from corollary 2.3 that such trajectories exist only if the interior of \( F_k \) has an equilibrium point and generically this happens only if condition A1 holds (corollary 2.1). As a particular case of the
analysis in the proof of theorem 2.6 and theorem 2.6', it then follows that \( \lambda_\alpha \) is obtained by substituting for \( p \) in (3.3) the (generically unique) equilibrium point of \( F_k \) given by corollary 2.1. Thus

\[
\lambda_\alpha = \frac{(N-1)}{\text{det} B^{(k,k)}} \left[ \sum_j a_{k,j} u_j^{(k)} \right] - \text{det} A^{(k,k)}. \tag{3.4}
\]

We now show that the quantity in [ ] in the last equation is just \(-u_k\). For ease of writing determinants, we consider the case \( k = s \).

\[
-u_s = -(-1)^s \left| \begin{array}{cccc}
-1 & a_{11} & a_{12} & \cdots & a_{1,s-1} \\
-1 & a_{21} & a_{22} & \cdots & a_{2,s-1} \\
& \vdots & \vdots & \ddots & \vdots \\
-1 & a_{s-1,1} & a_{s-1,2} & \cdots & a_{s-1,s-1} \\
-1 & a_{s1} & a_{s2} & \cdots & a_{ss-1}
\end{array} \right| 
\]

\[
= (-1)^{s-1} \left| \begin{array}{cccc}
-1 & a_{s1} & a_{s2} & \cdots & a_{s,s-1} \\
-1 & a_{s1} & a_{s2} & \cdots & a_{s,s-1} \\
& \vdots & \vdots & \ddots & \vdots \\
-1 & a_{s1} & a_{s2} & \cdots & a_{s,s-1} \\
-1 & a_{s1} & a_{s2} & \cdots & a_{s,s-1}
\end{array} \right| 
\]

\[
= -\text{det} A^{(s,s)} - a_{s1} \left| \begin{array}{cccc}
-1 & a_{s1} & a_{s2} & \cdots & a_{s,s-1} \\
-1 & a_{s1} & a_{s2} & \cdots & a_{s,s-1} \\
& \vdots & \vdots & \ddots & \vdots \\
-1 & a_{s1} & a_{s2} & \cdots & a_{s,s-1} \\
-1 & a_{s1} & a_{s2} & \cdots & a_{s,s-1}
\end{array} \right| 
\]

\[
= -\text{det} A^{(s,s)} + a_{s2} \left| \begin{array}{cccc}
-1 & a_{s2} & a_{s3} & \cdots & a_{s,s-1} \\
-1 & a_{s2} & a_{s3} & \cdots & a_{s,s-1} \\
& \vdots & \vdots & \ddots & \vdots \\
-1 & a_{s2} & a_{s3} & \cdots & a_{s,s-1} \\
-1 & a_{s2} & a_{s3} & \cdots & a_{s,s-1}
\end{array} \right| 
\]

\[
= -\ldots (-1)^{s-1} a_{s,s-1} \left| \begin{array}{cccc}
-1 & a_{s,s-1} & a_{s,s} & \cdots & a_{s,s-1} \\
-1 & a_{s,s-1} & a_{s,s} & \cdots & a_{s,s-1} \\
& \vdots & \vdots & \ddots & \vdots \\
-1 & a_{s,s-1} & a_{s,s} & \cdots & a_{s,s-1} \\
-1 & a_{s,s-1} & a_{s,s} & \cdots & a_{s,s-1}
\end{array} \right| 
\]

\[
= -\text{det} A^{(s,s)} + \sum_{j=1}^{s-1} a_{s,j} u_j^s. \tag{3.5}
\]
Here we have used the notation that if $M$ is an $n \times n$ matrix then $M^{(s,q)}$ is an $n \times (n - 1)$ matrix obtained from $M$ by removing its $q^{th}$ column. In the last line we have used the expression

$$u_{j}^{(s)} = \text{Cofactor of}(B_{0,j}^{(s,q)}) = (-1)^{j} \begin{pmatrix} -1 \\ -1 \\ \vdots \\ (A(s,q))^{(s,J)} \\ -1 \\ -1 \end{pmatrix}. \quad (3.6)$$

Therefore

$$\lambda_{\alpha} = -\frac{(N - 1)}{\det B^{(k,s)}} u_{k} \equiv \lambda. \quad (3.7)$$

Since $\lambda$ is a time average along a trajectory, if it is positive it means that $\lambda_{\alpha}(t)$ must have been positive for a sufficiently large subset of the trajectory. At all these times the trajectory must therefore have been unstable with respect to perturbations that take it away from $F_k$. Therefore we have proved

**Theorem 3.1** All trajectories in the face $F_k$ that do not converge to its relative boundary are unstable with respect to perturbations that take them away from $F_k$ if the r.h.s. of (3.7) is greater than zero. $\square$

This theorem covers periodic cycles and other attractors of $F_k$ that do not converge to its relative boundary.

Note that $\lambda_{\alpha}$ is independent of $\alpha$ and is expressed completely in terms of the payoff matrix. It also coincides with the transversal eigenvalue at the equilibrium point of $F_k^\alpha$ in PRD (compare with section 19.5 of Hofbauer and Sigmund, 1988). This is because the equilibrium point of $F_k^\alpha$ in GRD is homogeneous and given by corollary 2.1.

### 3.0.2. Stability of the Corners of $F_k$

By definition, at every corner of $J^N$ each agent pursues a pure strategy. Note that two agents using the same strategy are indistinguishable otherwise. Thus the key feature of a corner is the $s$-vector of non-negative integers $n = (n_1, \ldots, n_s)$ where $n_i$ is the number of agents using strategy $i$ in the given corner equilibrium, $1 \leq i \leq s$ (thus $\sum_i n_i = N$). Two corner equilibria with same associated $n$ vector are interchangeable, since they differ only in the identity of the agents, irrelevant for our purposes. On $F_k$, $n_k = 0$. On such a corner $n$, $\lambda_{\alpha}(n)$ depends on $\alpha$ only through $I$, the strategy pursued by the $\alpha^{th}$ agent. It is easy to see that

$$\lambda_{\alpha}(n) = P_k - P_I - h_{kI}, \quad (3.8)$$

where $P_j \equiv \sum_{i=1}^{s} a_{ij} n_i$ and $h_{ij} \equiv a_{ij} - a_{jj}$. There are thus at most $s - 1$ distinct eigenvalues at a corner of $F_k$. The condition for it to be unstable with respect to perturbations away from $F_k$ is that the largest of them is greater than or equal to zero.

We are interested in conditions on $A$ such that all corners of $F_k$ are unstable. For this purpose we will now study in detail the cases $s = 2, 3$. Before turning to
this analysis, note the following point: If a constant is added to all elements of a column of \(A\), the r.h.s. of (1.1) and (1.2) is unchanged because of cancellations between the two terms. Thus one can shift each column of \(A\) by a constant without affecting the dynamics. By choosing the constant in the \(j^{th}\) column to be \(a_{jj}\) we arrive at the matrix \(A' = (h_{ij}) = (a_{ij} - a_{jj})\) whose diagonal entries are zero. All conclusions about PRD or GRD are unaltered whether one works with the payoff matrix \(A\) or \(A'\). This includes the location and stability of equilibria.

Introduce the following

**Definition:** \(A\) is diagonally subdominant if \(a_{ii} < a_{jj} \forall j \neq i, \{i,j\} \subset S.\)

That is, \(h_{ij} > 0 \forall i \neq j.\) Note that the PRD with the matrix \(A'\) is then called a 'catalytic network' (see Section 20.4, Hofbauer and Sigmund, 1988).

\[s=2\]

In this case \(F_1\) and \(F_2\) are themselves both corners of \(J^N.\) There is one eigenvalue \(\lambda\) at each corner, and from (3.8) it follows that for \(F_1\) the eigenvalue is \(\lambda = (N - 1)h_{12}\) and for \(F_2, \lambda = (N - 1)h_{21}.\)

Therefore if \(A\) satisfies the condition

\[\textbf{A2: } \text{A is diagonally subdominant,}\]

then for \(s = 2, F_1\) and \(F_2\) are both unstable for a community of two or more agents. The condition \(\textbf{A2}\) will appear repeatedly in the subsequent analysis. Note that \(u_1 = -h_{12}, u_2 = -h_{21},\) and \(\det B = -(h_{12} + h_{21})\) are all negative if \(\textbf{A2}\) holds, hence diagonal subdominance implies \(\textbf{A1}\) or the existence of an equilibrium point in the interior of \(J^N.\) This equilibrium point is given (theorem 2.1) by \(p^\alpha = \frac{1}{h_{12} + h_{21}}(h_{12}, h_{21})\) for all \(\alpha,\) and by theorem 2.6', the trajectories \(p(t)\) that do not converge to the boundary of \(J^N\) converge to this point in the Cesaro sense.

\[s=3\]

For \(s = 3, \textbf{A2}\) no longer implies \(\textbf{A1};\) the latter is an independent condition.

**Lemma 3.2** For \(s = 3,\) if both \(\textbf{A1}\) and \(\textbf{A2}\) hold, then all trajectories in the interior of each \(F_k\) that do not converge to its boundary are unstable. Further, there exists a positive number \(N_0\) depending on \(A\) such that for \(N > N_0\) all corners of \(F_1, F_2, F_3\) are also unstable (Borkar, Jain and Rangarajan, 1998).

The first part follows from the analysis in Gadgil, Nanjundiah and Gadgil, 1980, section 5, where it is shown that under \(\textbf{A1,A2}\) for \(s = 3 \bar{\lambda}_\alpha\) is positive. Therefore the condition for theorem 3.1 is satisfied. (See also Hofbauer, Schuster, 1988).
which states that for \( s = 3 \), catalytic networks satisfying A1 are permanent. Permanence of PRD implies the positivity of transversal eigenvalues \( \bar{\lambda}_\alpha \).) For completeness we give a proof here, which will also be useful in the sequel. Under A1 and A2 the sign of the \( u_i \) is determined by the sign of \( \det A' \) (this is true
for any $s$. To see this consider the representation $A'$ so that the payoff $x_0' = \sum_{i,j} x_i h_{ij} x_j$ to each pure strategy at the IEP of PRD is, by $A_2$, a sum of positive terms. Since from (2.4) $x_0' = \det A'/\det B'$, this means $\text{sgn} \det B' = \text{sgn} \det A'$. Now $\det B' = \det B$ for any $s$. This is evident upon adding $a_{jj}$ times the first column of $B$ to its $j$th column for every $j$, whereby in (2.2) $A$ gets converted to $A'$ without change of determinant on both sides. But from $A_1$ and (2.5) all $u_i$ have the same sign as $\det B$, hence all $u_i$ have the same sign as $\det A'$. For $s = 3$, $\det A' = h_{12} h_{23} h_{31} + h_{13} h_{32} h_{21}$ is manifestly positive under $A_2$ and hence $\det B$ and $u_1, u_2, u_3$ are all positive. Also, since each $A^{(k,k)}$ is a $2 \times 2$ diagonally subdominant matrix, from the remarks above for $s = 2$, it is evident that $\det B^{(k,k)} < 0$ for each $k$. Thus $\lambda_k > 0$ for every $k$ and theorem 3.1 implies that all trajectories in each $F_k$ that do not converge to its relative boundary are unstable with respect to perturbations away from $F_k$.

Now consider the stability of corner equilibrium points of $F_k$. For concreteness consider $F_3$. Corners of $F_3$ are of two types,

Case 1: only one strategy survives at the corner. Then $n = (N, 0, 0)$ or $(0, N, 0)$. In the former case (3.8) implies $\lambda = (N - 1) h_{31}$ and in the latter case $\lambda = (N - 1) h_{32}$. By $A_2$ both corners are unstable.

Case 2: Both strategies 1 and 2 survive at the corner of $F_3$. Then $n = (n_1, n_2, 0)$ with both $n_1$ and $n_2$ positive integers and $n_1 + n_2 = N$. There are then two eigenvalues from (3.8), $\lambda_1 = h_{31} n_1 + h_{32} n_2 - h_{12} n_2 - h_{31}$, and $\lambda_2 = h_{31} n_1 + h_{32} n_2 - h_{21} n_1 - h_{32}$. Let us assume that this corner is stable, hence both $\lambda_1, \lambda_2$ are negative. The condition $\lambda_1 < 0$ (upon eliminating $n_1 = N - n_2$ reduces to $h_{12} + h_{31} - h_{32}) n_2 > (N - 1) h_{31}$. Since $n_2, N - 1, h_{31}$ are all positive this means that the combination $h_{12} + h_{31} - h_{32}$ is also positive, and

$$\frac{(N - 1) h_{31}}{h_{12} + h_{31} - h_{32}} < n_2. \quad (3.9)$$

Similarly $\lambda_2 < 0$ implies that $h_{21} + h_{32} - h_{31}$ is positive (as can be seen by eliminating $n_2$) and further,

$$n_2 < \frac{(N - 1)(h_{21} - h_{31})}{h_{21} + h_{32} - h_{31}} + 1. \quad (3.10)$$

Combining the two, we get

$$\frac{(N - 1) h_{31}}{h_{12} + h_{31} - h_{32}} < \frac{(N - 1)(h_{21} - h_{31})}{h_{21} + h_{32} - h_{31}} + 1, \quad (3.11)$$

which can be rearranged into the form

$$(N - 1)[h_{12} + h_{32} + h_{31} h_{21}] < (h_{12} + h_{31} - h_{32}) (h_{21} + h_{32} - h_{31}). \quad (3.12)$$

But the quantity in $[ ]$ on l.h.s. of this inequality is just $u_3$ (as evaluated from the definition (2.3)), which is positive. Thus we have

$$N < \frac{(h_{12} + h_{31} - h_{32}) (h_{21} + h_{32} - h_{31})}{u_3} + 1. \quad (3.13)$$

Note that the r.h.s. is a function of $A$ alone and is finite, say $N_0(A)$. If $N$ is chosen larger than $N_0(A)$, this inequality is violated. That is, for $N > N_0(A)$, the corner of $F_3$ under consideration cannot be stable. We have thus proved that under $A_1, A_2$, all corners of $F_3$ are unstable for $N > N_0(A)$. Similarly one may
consider $F_1, F_2$, which will yield the same result but with different finite bounds in place of $N_0(A)$. We can henceforth use $N_0$ for the largest of the three. Thus we have shown that for $s = 3$ under A1, A2 there exists a finite $N_0$ depending on the payoff matrix such that for $N > N_0$ all corners of $F_1, F_2, F_3$ are unstable. □

This however does not yet prove that all trajectories in $F_k$ are unstable for sufficiently large $N$ (in what follows the phrase 'sufficiently large $N$' will mean '$N > N_0$ for some finite $N_0$ depending on $A$'). This is because unlike $s = 2$, for $s = 3$ $F_k$ is not just the union of its relative interior and corners, it also contains other subfaces where one or more agents have opted out of a pair of strategies (and different agents can choose different pairs to opt out of).

To complete the proof, let us consider the homogeneous sector of $F_3$, $p^a = (x, 1 - x, 0)$ for all $a$. In this sector all eigenvalues (3.3) are equal and reduce to $\lambda$ given by

$$\frac{\lambda}{(N - 1)} = h_{32} + (h_{31} - h_{32} - h_{12} + h_{21})x + (h_{12} + h_{21})x^2.$$  (3.14)

$\lambda$ has a minimum $\lambda_{\min}$ at

$$x = c_1 = \frac{h_{32} + h_{12} + h_{21} - h_{31}}{2(h_{12} + h_{21})}.$$  (3.15)

given by

$$1/(N - 1)\lambda_{\min} = h_{32} - (h_{12} + h_{21})c_1^2$$
$$= \frac{1}{4(h_{13} + h_{31})} \left[ 2u_3 + 2h_{31}h_{32} - (h_{31} - h_{21})^2 - (h_{32} - h_{22})^2 \right].$$  (3.16)

Similarly if we had considered the faces $F_1$ and $F_2$ we would have got the respective $\lambda_{\min}$'s,

$$1/(N - 1)\lambda_{\min}|_{F_1} = \frac{1}{4(h_{23} + h_{33})} \left[ 2u_1 + 2h_{13}h_{12} - (h_{12} - h_{22})^2 - (h_{13} - h_{23})^2 \right],$$

$$1/(N - 1)\lambda_{\min}|_{F_2} = \frac{1}{4(h_{13} + h_{33})} \left[ 2u_2 + 2h_{21}h_{23} - (h_{21} - h_{31})^2 - (h_{23} - h_{13})^2 \right].$$  (3.17)

Define the following condition on the payoff matrix:

A3: $\lambda_{\min}|_{F_i} > 0$ for each face $F_1, F_2, F_3$.

Now we can state the following theorem, the proof of which is given in Appendix A.

Theorem 3.2 For $s = 3$ if the payoff matrix satisfies A1, A2, A3, then (1.2) exhibits diversity for sufficiently large $N$.

In this section we have discussed criteria for the community to be fully diversified. Sufficient conditions for the instability of non-diversified faces $F_k$ were given for communities of $N$ agents and $s = 2, 3$ strategies, and partial results were presented for the general case of $s$ strategies. Parallels with the conditions for permanence of the corresponding PRD dynamics were noted. It may be of
interest to explore these parallels further. In particular, if condition A3 can be eliminated from the proof of theorem 3.2 along the lines mentioned in Appendix A, it will be tempting to conjecture that GRD exhibits diversity for sufficiently large $N$ if PRD with the same payoff matrix is permanent.

An unusual feature of the GRD diversity is that under suitable conditions satisfied by the payoff matrix there is a critical number of agents $N_0$ above which diversity is guaranteed to appear. There is no analogue of this in PRD. It is interesting to trace the origin of this lower bound on the number of agents. As it stands, in GRD no agent plays against herself; the $\beta = \alpha$ term in (1.2) is excluded. If the $\beta = \alpha$ term is added to the r.h.s. of (1.2), then the lower bound on $N$ required in the above theorems disappears. To see this (using the notation from Appendix A) note that then $y^\alpha$ and $x^\alpha \gamma$ are replaced by $w = (1/N) \sum_{i=1}^N \beta_i^\alpha$ and (A.2) gets modified to $\lambda_\alpha - \lambda_\gamma = N(h_{12} + h_{21})(x^\gamma - x^\alpha)(x_i^{(3)} - w)$. Then at the boundaries of the region of $\lambda_\alpha$ dominance considered where we got $\lambda_\alpha/(N-1) = x_i^{(3)} + O(1/N)$, we now get $\lambda_\alpha/N = x_i^{(3)}$ exactly without any $O(1/N)$ corrections. Therefore the clause "sufficiently large $N$" is no longer necessary anywhere. One might be tempted to say that a sufficiently large community in some sense nullifies the effect of excluding the payoff from an agent to herself. This may be true; however, as will be made explicit in the next section, this 'self exclusion' is crucial for specialization.

It is also worth noting that the second half of Lemma 3.2 in conjunction with the proof of Theorem 2.7 implies that under A1, A2, and for sufficiently large $N$, every attractor that is asymptotically stable in $F_k$ will be unstable with respect to perturbations away from $F_k$.

4. CORNER EQUILIBRIA OF GRD:
DIVERSITY WITH SPECIALIZATION

We now present the evidence for specialization in GRD. Note that theorem 2.3 is quite a powerful result in this regard. It rules out any compact set in the relative interior of any face from being a stable attractor of the dynamics. The only asymptotically stable compact attractors allowed are corners, where, by definition, the community is fully specialized. However the theorem does not rule out non-compact attractors in relative interiors of faces or heteroclinic cycles. Theorem 2.7 rules out the former; it tells us that all asymptotically stable attractors must include corners. We have augmented the evidence for corners by the following numerical investigation for $s = 3$. Since one element (say the diagonal) in every column of $A$ can be chosen to be zero without loss of generality, for $s = 3$ $A$ has only six independent elements. Ten payoff matrices were generated by randomly selecting ten points from $[0, 1]^6$, the components of each point providing the six needed offdiagonal elements of a payoff matrix. (1.2) was integrated numerically for long times for each payoff matrix with ten randomly chosen initial conditions in $J^N$, with $N = 5$ and 10. (Thus with each value of $N$, 100 trajectories were generated.) For $N = 5$, 90 out of the 100 trajectories converged to a corner of $J^L$. The 10 trajectories that did not were for different initial conditions with the same payoff matrix. In these 10 cases we found that the trajectories spent increasingly long times near a set of corners, moving
rapidly, when they did, between successive corners. As mentioned at the end of section 2, this behaviour is strongly suggestive of heteroclinic cycles being the attractors in this case (the simulation was turned off when the period of stasis near corners became too long). With $N = 10$, all 100 trajectories converged to a corner of $J^{10}$, including those corresponding to the payoff matrix $A$ that for $N = 5$ had given different results. This suggests that while heteroclinic cycles can be present, they are rare, and tend to disappear for larger values of $N$, leaving only corner attractors. While more work is necessary to quantify the rarity of non-corner attractors, we regard the above theorems and numerical results as strong evidence that evolution under (1.2) typically leads to a fully specialized community.

In this section we study corners of GRD with particular emphasis on the question: which corners of $J^N$ are favoured by the dynamics? We will find that under suitable circumstances, the favoured corners are ‘close’ to the PRD interior equilibrium point, in that the fraction of agents pursuing the pure strategy $i$ at the favoured corners is close to the $x_i$ given by (2.1). Crucial to this analysis is the stability of corners in GRD.

4.1. Stability of Corner Equilibria

The following theorem proved in Weibull (1995) will be useful to write down conditions for asymptotic stability of corner equilibria.

**Theorem 4.1** An equilibrium point is asymptotically stable if and only if it is a strict Nash equilibrium.

As noted earlier a corner of $J^N$ is characterized by the vector $\mathbf{n}$ whose component $n_i$ equals the number of agents pursuing pure strategy $i$ at that corner. The following then is a characterization of asymptotic stability of a corner equilibrium in terms of its associated vector $\mathbf{n}$:

**Theorem 4.2** A corner equilibrium is asymptotically stable if and only if the associated $\mathbf{n}$ satisfies:

$$(n_i - 1)a_{ii} + \sum_{j \neq i} n_j a_{ij} > (n_i - 1)a_{ki} + \sum_{j \neq i} n_j a_{kj} \quad \forall \ k \neq i, \ 1 \leq i \leq s,$$  

(4.1)

with the understanding that if $n_i = 0$ for some $i$, the inequalities in which $(n_i - 1)$ occurs are dropped.

This can be proved in two ways. One is to do the usual stability analysis of the linearized system around the said equilibrium. In this case, the difference between the right hand and left hand sides of Eq. (4.1) gives precisely the eigenvalues of the linearized system, which then must be strictly negative. Alternatively, note that the inequality is tantamount to the statement that an agent using strategy $i$ strictly lowers her payoff if she switches her strategy to $j$, all other agents’ strategies being kept constant. This being the definition of a strict Nash equilibrium in our context, Eq. (4.1) can be read off Theorem 4.1.

Also, observe that if all $n_i > 0$, then there are $s(s - 1)$ inequalities to be satisfied. If some $n_i = 0$, the number is correspondingly lower. Thus a priori, things seem to be loaded against diversification. As we saw in section 3 in our analysis of the corners of $F_k$, some further structure had to be imposed on $A$ in order to get diversification.
4.2. LARGE \( N \) LIMIT OF GRD

First we define a fully diversified corner equilibrium point (FDCEP) of GRD to be a corner equilibrium point with none of the \( n_i \)'s (in the associated vector \( n \)) equal to zero. We prove the following theorem (Borkar, Jain and Rangarajan, 1998) on the relative locations of asymptotically stable FDCEP's and their relation to the interior equilibrium point (IEP) of PRD.

**Theorem 4.3** If \( A \) is such that PRD admits an IEP \( x \), i.e., if it satisfies condition A1 [cf. Section II], then for the corresponding GRD with \( N \geq s \) agents,

(i) for any pair \((n, n')\) of asymptotically stable FDCEP's, all components of the difference \( n' - n \) are bounded by a function of \( A \) alone, not of \( N \), and

(ii) \( \forall \) asymptotically stable FDCEP, \( \lim_{N \to \infty} \frac{n_i}{N} = x_i \).

The proof of the theorem is given in Appendix B. We now briefly discuss the consequences of this theorem. Recall the observations in section 2 that at the dynamical level GRD is quite different from PRD even in the limit of large number of agents. For example, one might have hoped that \( \dot{x}_i \equiv (1/N) \sum_{\alpha=1}^{N} p_{i\alpha} x_\alpha \) satisfies the PRD equation in the large \( N \) limit, but as mentioned in section II B, that is not the case. Furthermore, the homogeneous IEP of GRD \( p = x \) is always unstable in GRD irrespective of whether \( x \) is stable in PRD or not. Nevertheless by the above theorem all the stable FDCEP’s of GRD correspond to the IEP \( x \) of PRD in the large \( N \) limit. Thus in a sense, we recover PRD “through the backdoor” in GRD, or literally “through the corners” of GRD. The theorem does not guarantee the existence of a stable FDCEP. But if a stable FDCEP does exist, its ‘closeness’ to the IEP of PRD is guaranteed, if the latter exists. Put another way, if (1.2) exhibits both specialization and diversity, and A1 holds, the small subset of FDCEP defined in theorem 4.3 will attract (after a small perturbation, if needed) all trajectories in \( J^N \).

4.3. CONDITIONS FOR THE EXISTENCE OF STABLE FULLY DIVERSIFIED CORNERS

It is instructive to consider the case \( s = 2 \). Explicit computation shows the following:

Case 1: \( a_{11} > a_{21} \) and \( a_{22} > a_{12} \): Both \((N,0)\) and \((0,N)\) are asymptotically stable, other corners are not.

Case 2: \( a_{11} > a_{21} \) and \( a_{22} < a_{12} \): \((N,0)\) is the only asymptotically stable corner.

Case 3: \( a_{11} < a_{21} \) and \( a_{22} > a_{12} \): \((0,N)\) is the only asymptotically stable corner.

Case 4: \( a_{11} < a_{21} \) and \( a_{22} < a_{12} \): \((n_1, n_2)\) is an asymptotically stable corners, where \( n_1 + n_2 = N \), \( n_1 \neq 0 \), \( n_2 \neq 0 \), and furthermore,

\[
\frac{(n_2 - 1)}{n_1} (a_{12} - a_{22}) < (a_{21} - a_{11}) < \frac{n_2}{(n_1 - 1)} (a_{12} - a_{22})
\] (4.2)
if \( n_2 < N - 1 \) and

\[
\frac{(n_2 - 1)}{n_1} (a_{12} - a_{22}) < (a_{21} - a_{11})
\]  \hspace{1cm} (4.3)

If \( n_2 = N - 1 \).

Cases 2 and 3 correspond to dominated strategies. (The cases with one or more equalities instead of inequalities has been disregarded as nongeneric. In any case, they are not difficult to handle.) The case of interest to us is the last one, which shows diversification. It can be shown that the necessary and sufficient condition for the solution \((n_1, n_2)\) with neither \(n_1\) nor \(n_2\) zero to be stable is that \(A\) is diagonally subdominant (condition \( A2 \)), and the solution is unique. Further all the non-FDCEP are then unstable (as was already mentioned in section 3).

We now consider conditions for the existence of stable FDCEP for higher \(s\). For \(s = 3, 4\) we have performed a computer search for stable FDCEP at all values of \(N\) up to 1000 for a large number of payoff matrices. We find that when \(A1, A2\) are satisfied most often we get stable FDCEP for sufficiently large \(N\), but not always. Thus \(A1, A2\) do not guarantee the existence of a stable FDCEP even for sufficiently large \(N\), and we must impose further conditions.

Before proceeding further, note that there is a potential redundancy in Eq. (4.1). To see this, rewrite Eq. (4.1) (assuming \(n_i > 0 \ \forall i\)) as

\[
a_{ii} - a_{ki} < \sum_j (a_{ij} - a_{kj})n_j < a_{ik} - a_{kk} \ \forall i \neq k.
\]  \hspace{1cm} (4.4)

Under diagonal subdominance, the rightmost (resp. leftmost) term is strictly positive (resp. negative). Now adding Eq. (4.4) for \((i, l)\) and \((l, k)\), \(i \neq l \neq k\), we get

\[
a_{ii} + a_{il} - a_{li} - a_{kl} < \sum_j (a_{ij} - a_{kj})n_j < a_{ii} + a_{lk} - a_{il} - a_{kk}.
\]  \hspace{1cm} (4.5)

The middle term is the same as in Eq. (4.4) above. Thus by combining inequalities, one may come up with Eq. (4.4) with alternative positive (resp. negative) numbers on the right (resp. left). By taking the minimum (resp. maximum) of all such possibilities, we settle for a reduced form of Eq. (4.4):

\[
-\varepsilon_{ik} < \sum_j (a_{ij} - a_{kj})n_j < \varepsilon_{ik}, \ \ i \neq k,
\]  \hspace{1cm} (4.6)

for suitable ‘minimal’ \(\varepsilon_{ik}\), \(\varepsilon_{ik} > 0\) which depend only on \(A\).

**Theorem 4.4** Suppose \(A\) is diagonally subdominant and PRD has an interior equilibrium. Then there exist \(N(p) \uparrow \infty\) and asymptotically stable diversified corner equilibria \(n^{(p)} = [n_1^{(p)}, \ldots, n_s^{(p)}]\) such that \(\sum_{j=1}^s n_j^{(p)} = N(p)\).

**Proof** Let \(x = (x_1, \ldots, x_s)\) be the interior equilibrium of PRD. Suppose \(\{x_i\}\) are rational. Write them as \(x_i = n_i/N, \ 1 \leq i \leq s\). Then for \(p \geq 1\), \(n_j^{(p)} = pn_j, \ 1 \leq j \leq s\), will satisfy \(\sum_j (a_{ij} - a_{kj})n_j^{(p)} = 0, \ \forall i \neq k\), implying Eq. (4.6). Thus the above choice of \(n^{(p)} = (n_1^{(p)}, \ldots, n_s^{(p)})\) and \(N(p) = pN\) will satisfy the claim.
If \( x_j \)'s are not rational, we are still done if we approximate them simultaneausly by rationals \( n_j^{(p)} / N(p) \), \( 1 \leq j \leq s \), with an error \( o(1/N(p)) \), as \( N(p) \to \infty \). This is because on dividing Eq. (4.6) through by \( N = \sum_j n_j \), the right hand side and left hand side approach zero as \((\text{constant}/N)\). Such an approximation is possible by a standard result in number theory (Theorem 200, p. 170, Hardy and Wright, 1979). □

This still falls short of our original aim of showing the existence of asymptotically stable diversified corner equilibria for all \( N \) sufficiently large. Rewrite Eq. (4.6) as

\[
-a + bN < C \begin{pmatrix} n_1 \\ n_2 \\ \vdots \\ n_{s-1} \end{pmatrix} < \bar{a} + \bar{b}N
\]

for suitably defined \( a, b, \bar{a}, \bar{b}, C \). (This is achieved by setting \( n_s = N - \sum_{i \neq s} n_i \) in Eq. (4.6) and rearranging terms.) Consider the inequality

\[
-a + bN < C \bar{z} < \bar{a} + \bar{b}N
\]

where \( \bar{z} \in \mathbb{R}^{s-1} \). For each \( N \), Eq. (4.8) specifies a volume element \( V(N) \) whose volume is independent of \( N \). In fact, \( V(N) \) is a translate of \( V(0) \).

**Theorem 4.5** If \( V(0) \) contains an axis-parallel unit cube in its interior, then there exist asymptotically stable diversified corner equilibria for all \( N \geq s \).

**Proof** This is immediate. □

5. DISCUSSION AND CONCLUSIONS

In this paper we have considered a generalization (Eq. (1.2)) of replicator dynamics as a model of a community of \( N \) interacting agents, each capable of pursuing any mix of strategies drawn from a set of \( s \) pure strategies. At any time each agent \( \alpha \) senses the aggregate mix of strategies being pursued by the rest of the community (namely the quantity \( \sum_{j \neq \alpha} p_{i,j}^\beta \)) and in response to this aggregate updates her own strategy mix \( p^\alpha \) to increase her individual payoff. This is thus a non-cooperative game in which agents act selfishly (each is concerned with increasing her own payoff without consideration of impact on others).
others of the community), locally (each agent updates only her immediate
and exhibit bounded rationality (no anticipation of others' strategy, merely a
response to the current aggregate behaviour of others based on simple rules).
Nevertheless the community as a whole seems to exhibit global organization
under certain circumstances. Here we would like to summarize previous as well
as our own mathematical results on this system, mention some future directions
and conjectures and discuss the implications of these mathematical results for
the nature of organization in this system.

The parameters of the model are $N$ and the $s \times s$ payoff matrix $A$. The model
reduces to the pure replicator dynamics, equation (1.1), in the homogeneous
sector, where all agents pursue the same mixed strategy. As shown in section
2 (theorem 2.4 and corollary 2.1) generically the equilibrium points of GRD in the interior of $J^N$ and the faces $F_k$ are unique, homogeneous, and coincide with the equilibrium points of PRD, when the latter exist. In fact generically all faces (including those that have no analogue in PRD) have unique equilibrium points in GRD if any (theorem 2.5) and all trajectories in a face that do not converge to the relative boundary of the face converge in the Cesaro sense to the unique equilibrium point of the face (theorem 2.6). These are properties GRD shares with PRD.

Specialization: Theorem 2.7 asserts that all asymptotically stable attractors of (1.2) must include corners, and the previously known theorems 2.3 and 4.1 that such attractors, if compact, can only be corners that are strict Nash equilibria. That is, a trajectory either eternally moves around in the relative interior of some face or the interior of $J^N$ coming arbitrarily close to its boundaries and corners (the case of non-compact attractor in the relative interior), in which case its time average (over long times) converges to the (generically) unique interior equilibrium point of that face (by theorem 2.6), or it converges to a corner of $J^N$. It is possible to construct payoff matrices for which there are no asymptotically stable corners in $J^N$, whereupon the former situation obtains.

However, numerical work with $s = 3, 4$ suggests that this happens rarely (i.e., in a relatively small region of $R_+^{N_+}$); for most payoff matrices asymptotically stable corners do exist for most values of $N$. Further, when asymptotically stable corners do exist, their basins of attraction cover most of $J^N$, i.e., trajectories typically flow into some such corner or the other. Thus corners seem to be the most common attractors in GRD (see beginning of section IV). These are numerical indications and need to be made more precise. In our interpretation of the model, a corner corresponds to the situation where each agent has specialized to some pure strategy or the other. The above evidence suggests that specialization of all the agents is the most common outcome in GRD. It is well known (see Weibull, introduction to chapter 5), that this property of (1.2) is a consequence of the 'self exclusion' property: the agent $\alpha$ excludes herself when she monitors the aggregate behaviour of the community (in (1.2) the term $\beta = \alpha$ is absent). This is also seen explicitly above in section 4 (see remark after the proof of theorem 4.3 in Appendix A). The justification of excluding the term $\beta = \alpha$ in (1.2) is that agents, e.g., firms in an economic web, do not compete with themselves.

Specialization with diversity: Individual trajectories in GRD are quite unlike PRD in that homogeneous trajectories are typically unstable with respect to inhomogeneous perturbations; variation among agents is generic. This gives rise to the new possibility in GRD of having diversity (all strategies represented in the community) with specialization. This is the situation where the dynamics converges to a corner in which the number $n_i$ of agents pursuing the pure strategy $i$ at that corner is nonzero for all strategies. It turns out that there is a strong quantitative constraint on the relative weight $n_i/N$ of each strategy at such corners. By theorem 4.3 $n_i/N$ is forced to be close to $z_i$ and equal to it in the large $N$ limit, where $z_i$ is given by (2.3) and is the relative weight of the $i$th strategy at the interior equilibrium point of PRD. This constraint is a consequence of the fine balance that exists for every agent at a strict Nash equilibrium; any
strategy switch for any agent reduces her payoff. This fine tuning, caused by the interaction of the agent with other agents, is a kind of organization exhibited by the system. Another way of looking at this is that there is a pattern in the departure from homogeneity: even the fully diversified corners (which are as inhomogeneous as any point can be) that are picked out by the dynamics to be asymptotically stable retain a strong memory of PRD. We have also shown that for any payoff matrix that admits an interior equilibrium point of PRD there is an infinite set of values of \( N \) at which such fully diversified corners are stable attractors (theorem 4.4).

**Guaranteeing diversity:** Even if fully diversified strict Nash equilibria exist, there could still exist other strict Nash equilibria that are not fully diversified, or other stable attractors in the faces \( F_k \). At such attractors, some strategy or the other would become extinct. In section 3 we have been interested in the conditions for the absence of such attractors, or conditions that would guarantee the survival of all strategies in the community. Specifically we have studied the conditions for trajectories in the faces \( F_k \) (which is the face where the \( k^{th} \) strategy becomes extinct) to become unstable. For trajectories that do not converge to the boundary of \( F_k \), the condition is given by theorem 3.1, namely, that the transversal eigenvalue \( \lambda_\alpha \) given by (3.7) be positive. In general for arbitrary trajectories the cases \( s = 2, 3 \) have been studied in detail. For \( s = 2 \), the condition \( A_2 \), or diagonal subdominance of the payoff matrix was found to be sufficient (section 3) and necessary (section 4) for the faces \( F_1 \) and \( F_2 \) to be unstable. For \( s = 3 \) we showed (theorem 3.2) that if the payoff matrix satisfies three conditions \( A_1, A_2, A_3 \), and the number of agents \( N \) is larger than a finite value \( N_0 \) that depends on the payoff matrix, then all points where some strategy or the other becomes extinct are unstable with respect to perturbations in which some agent or the other starts exploring the extinct strategy. In particular, note that conditions on the payoff matrix alone are not enough, a condition on the minimum size of the community is also needed.

**Self-organization:** As remarked after theorem 4.3, if (1.2) exhibits both specialization and diversity, for arbitrary initial conditions (upto perturbations) the final state gets locked into a very small subset of fully diversified corners where the fraction of agents at a particular pure strategy is 'close' to the PRD equilibrium point. This represents a kind of self organization that arises in the community in that the final state is highly fine tuned without any fine-tuning of the parameters or initial conditions. As mentioned earlier, specialization seems to be a generic property of GRD. Further, the sufficient conditions for diversity found for \( s = 2, 3 \) are only inequalities (and not equalities) among the payoff matrix elements (and the same can be expected for higher \( s \)). Thus diversity is a structurally stable property of GRD.

In this context the following collective behaviour of the community is also worth noting. Let (1.2) possess specialization and diversity. Let \( P \) be a point in \( F_k \) at which only one of the \( N \) transversal eigenvalues \( \lambda_\alpha \) in (A.1) is positive. Then, at this point it is advantageous for only one agent, \( \alpha \), to move to the \( k^{th} \) strategy. Now imagine a small perturbation to the community in which all the agents are moved slightly out of \( F_k \) at \( P \). Initially only one agent, \( \alpha \), would like
to move away from $F_k$; others would want to move back to $F_k$. However, we know that the final state in this case must be the stable fully diversified corner(s) given by theorem 4.3, in which a finite fraction (by definition) of the agents play the pure strategy $k$. Thus the small perturbation, and movement away from $F_k$ by a single agent results in a global movement (of a significant fraction) of the whole community.

**Innovation from instability:** The above is immediately relevant to the question: when does a society accept an innovation? For consider a community of a large number of agents but with only two strategies, 1 and 2, at a stable corner where $n_1$ agents pursue the pure strategy 1 and $n_2 = N - n_1$ agents the pure strategy 2 (neither $n_1$ nor $n_2$ is zero). Since this corner is assumed stable, the $2 \times 2$ matrix $A$ satisfies condition A2 (diagonal subdominance). Now imagine that a new strategy 3 arises thereby enlarging the payoff matrix to a $3 \times 3$ matrix $A'$ containing $A$ as a $2 \times 2$ block. In the new context the earlier state of the community will be described by a three vector $n = (n_1, n_2, 0)$, which is in the face $F_3$. Now if the new payoff matrix satisfies $A1, A2, A3$, and $N$ is sufficiently large, then, from theorem 3.2, this configuration is unstable, and at least one of the transversal eigenvalues, say $\lambda_3$, is positive. Thus if the community were to be perturbed slightly from $F_3$ at this point, then as discussed in the previous para, the perturbation would grow until it settles down in another attractor. The new attractor if described by theorems 2.6' or 4.3 would have the property that a finite fraction of the population pursues the new strategy: the innovation has been accepted by the society. Thus the conditions $A1, A2, A3$ of theorem 3.2 indicate what the payoffs of a new strategy should be with respect to the existing ones, if the new strategy is to be guaranteed acceptance.

At this point we have a sufficient condition for diversity in GRD only for $s = 2, 3$. It is of interest to obtain necessary and sufficient conditions for general $s$.

**Selection of a subset of strategies from a large initial strategy set:** If we start from a large payoff matrix as describing the possible set of strategies available to a given community, and start the system with some subset of strategies populated, then how will the population evolve? Dominated strategies would disappear, some strategies that were unrepresented in the population earlier would appear as 'acceptable innovations' etc. The deterministic dynamics however, has no provision for initiating as yet untried strategies. Thus one has to enlarge the scope of our model by, e.g., introducing 'random mutation' or 'noise'.

**APPENDIX A**

**Theorem 3.2** For $s = 3$ if the payoff matrix satisfies $A1, A2, A3$, then (1.2) exhibits diversity for sufficiently large $N$. 
Proof: We need to show that under the conditions mentioned all trajectories in the faces \( F_1, F_2, F_3 \) are unstable with respect to perturbations away from these faces. Consider a point \( p \) in \( F_3 \); \( p^a \equiv (x^a, 1 - x^a, 0) \). At this point, from (3.3)

\[
\frac{1}{(N - 1)} \lambda_a(p) = \frac{1}{(N - 1)} \left[ \sum_{\beta \neq a} h_{\beta} \sum_{j} y_{\beta,j}^a - \sum_{\beta \neq a} \sum_{K,j} K_{\beta,K} h_{K,j} y_{\beta,j}^a \right]
= \sum_{j} h_{3,j} y_{3,j}^a - \sum_{j} \sum_{K,j} K_{3,K} h_{K,j} y_{3,j}^a
= h_{32} - h_{12} x^a + (h_{31} - h_{32} - h_{21}) y^a + (h_{12} + h_{21}) x^a y^a
\tag{A.1}
\]

where \( y^a \equiv \frac{1}{(N - 1)} \sum_{\beta \neq a} p^\beta \equiv (y^a, 1 - y^a, 0) \). Since the \( \lambda_a \) depend upon \( p \) and they are in general not all equal, we can ask for the largest eigenvalue \( \lambda_a \) at any point of \( F_3 \). In fact different \( \lambda_a \) will dominate (i.e., be the largest eigenvalue) in different regions of \( F_3 \). Let us fix \( \alpha \) and identify the region \( F_3^\alpha \) of \( F_3 \) in which \( \lambda_a \) is dominant. In this region, if \( \lambda_a \) is positive all trajectories passing through this region are unstable from perturbations in which the \( \alpha \)th agent spends a small fraction of time exploring strategy 3.

We will show that under \( A_1, A_2, A_3 \) the minimal value of \( \lambda_a \) in its region of dominance is always positive. The proof does not depend on the \( \alpha \) chosen. Hence for any \( \alpha \), the minimal value of \( \lambda_a \) in the region of \( F_3 \) where it dominates is positive. Since for every point in \( F_3 \) there will always be some \( \lambda_a \) that will be the largest, this proves that the whole of \( F_3 \) is unstable under perturbations in which some agent or the other starts exploring strategy 3.

Consider the set \( A_\alpha = \{1, 2, \ldots, N\} - \{\alpha\} \) which labels all agents other than \( \alpha \). Let us write the \( x^\prime \)'s for all these agents in ascending order: \( 0 \leq x^\prime_1 \leq x^\prime_2 \leq \ldots \leq x^\prime_{N-1} \leq 1 \), where \( \{y_1, \ldots, y_{N-1}\} \) is some permutation of the elements of \( A_\alpha \). It is convenient to partition \( F_3 \) into the following five subsets:

I: \( 0 \leq x^a < x^\prime_1 \) with \( 0 < x^\prime_1 \leq 1 \),
II: \( x^a = x^\prime_1 \) with \( 0 \leq x^\prime_1 \leq 1 \),
III: \( 0 \leq x^\prime_1 < x^a < x^\prime_{N-1} \leq 1 \),
IV: \( x^a = x^\prime_{N-1} \) with \( 0 \leq x^\prime_{N-1} \leq 1 \), and
V: \( x^\prime_{N-1} < x^a \leq 1 \) with \( 0 \leq x^\prime_{N-1} \leq 1 \).

It will be clear upon slight reflection that all of \( F_3 \) is covered by these five sets, assuming, of course, that the indices \( \{y_1, \ldots, y_{N-1}\} \) are allowed to go over all permutations of the elements of \( A_\alpha \). We will consider these five regions for a fixed (but arbitrary) such permutation, and show that \( \lambda_a \) is positive in each of these regions wherever it is the dominant eigenvalue, under the conditions of theorem 3.2.

One crucial property of \( \lambda_a \) will be used repeatedly in the proof: If one substitutes \( y^a = x^{(3)}_1 = h_{12}/(h_{12} + h_{21}) \) in the last expression in (A.1), one finds \( \lambda_a/(N - 1) = u_3/(h_{12} + h_{21}) \), which is positive under \( A_1 \) and \( A_2 \). Furthermore, if \( y^a \) differs from \( x^{(3)}_1 \) by a term of \( O(1/N) \), \( \lambda_a/(N - 1) \) will also differ from \( u_3/(h_{12} + h_{21}) \) by a term of \( O(1/N) \) and hence will be positive under \( A_1 \) and \( A_2 \) for \( N \) sufficiently large.

To find the region \( F_3^\alpha \) where \( \lambda_a \) dominates, note that from (A.1), for \( \alpha \neq \gamma \),

\[
\lambda_a - \lambda_\gamma = \left( x^\gamma - x^a \right) \left[ h + (N - 2)(h_{12} - (h_{12} + h_{21})x^\alpha y^a) \right]
= (N - 2)(h_{12} + h_{21})(x^\gamma - x^a)(c_0 - z^\alpha), \tag{A.2}
\]
where \( h \equiv h_{31} - h_{32} + h_{12} - h_{31} \), \( x^{\alpha \gamma} \equiv 1/(N - 2) \sum_{\beta \neq \alpha, \beta \neq \gamma} p^{\beta} \equiv (x^\gamma, 1 - z^\gamma, 0) \), and \( c_0 \equiv 1/[(h_{12} + h_{31})[h_{12} + h/(N - 2)] \]. Note that \( c_0 \) differs from \( x_1^{(3)} = h_{12}/(h_{12} + h_{21}) \) only by a term of \( O(1/N) \). This means that \( \lambda_\alpha = \lambda_{\alpha} \) if either \( x^\alpha = x^\gamma \) or \( c_0 = x^{\alpha \gamma} \), and \( \lambda_\alpha \) is larger than all other eigenvalues in the region where, given any \( \gamma \neq \alpha \), either

(i) \( x^\gamma - x^\alpha > 0 \) and \( c_0 - x^{\alpha \gamma} > 0 \), or,

(ii) \( x^\gamma - x^\alpha < 0 \) and \( c_0 - x^{\alpha \gamma} < 0 \). \hspace{1cm} (A.3)

Note that \( (N - 1)y^\alpha = (N - 2)x^{\alpha \gamma} + x^\gamma \), hence \( y^\alpha \) differs from \( x^{\alpha \gamma} \) by a term of \( O(1/N) \).

Consider first the region III. In the region of \( \lambda_\alpha \) dominance, \( x^{\gamma} < x^\alpha \) implies that \( c_0 - x^{\alpha \gamma} < 0 \), or, since \( x^{\alpha \gamma} = \left(\frac{N - 1}{N - 2}\right)y^\alpha - \frac{x^\gamma}{N - 2} \), that \( y^\alpha > c_0^{(1)} \equiv \left(\frac{N - 2}{N - 1}\right)c_0 + \frac{x^\gamma}{N - 1} \). Similarly \( x^\alpha < x^{\alpha \gamma} \) in the region of \( \lambda_\alpha \) dominance implies that \( y^\alpha < c_0^{(1)} \equiv \left(\frac{N - 2}{N - 1}\right)c_0 + \frac{x^\gamma}{N - 1} \). Thus \( y^\alpha \) is boxed inside an interval of size \( O(1/N) \) around \( \left(\frac{N - 2}{N - 1}\right)c_0 \), and since \( c_0 \) differs from \( x_1^{(3)} \) by \( O(1/N) \), it follows that \( y^\alpha \) is boxed inside an interval of size \( O(1/N) \) around \( x_1^{(3)} \). Thus by the property mentioned earlier, it follows that under A1 and A2 and for sufficiently large \( N \), \( \lambda_{\alpha}/(N - 1) \) is positive in the region of III where \( \lambda_\alpha \) is the dominant eigenvalue.

Note that from (A.1) it follows that \( \lambda_\alpha \) considered as a function of two real variables \( x^\alpha \) and \( y^\alpha \) in any region of the \( (x^\alpha, y^\alpha) \) plane will take its minimum value at the boundary of the region. This is because the function \( f(x, y) = a + bx + cy + dzy \) of two real variables \( x \) and \( y \) \((a, b, c, d \text{ real}, d \neq 0\) has a unique extremum at \( (x, y) = (-c/d, -b/d) \) and this is always a saddle point since the second derivative matrix of \( f \) has eigenvalues \(+d\). Thus to locate the minimum value of \( \lambda_\alpha \) in any region of \( F_3 \), we only need to look at the boundary of this region's projection on the \( (x^\alpha, y^\alpha) \) plane.

Before turning to the remaining four regions it is instructive to look at the two dimensional subset of \( F_3 \) in which all the \( x^\gamma \) are equal, \( i = 1, 2, \ldots, N - 1 \). Then \( x^{\gamma_1} = x^{\gamma_2} = \cdots = x^{\gamma_{N - 1}} = x^{\alpha \gamma} = y^\alpha \). This subset of \( F_3 \) projects onto the unit square in the \( (x^\alpha, y^\alpha) \) plane (the \( x^{\alpha} \) and \( x^{\gamma} \) belong to \([0, 1]\)). The part of the unit square in which \( \lambda_{\alpha} \) is the largest eigenvalue is denoted by \( R \). This subset \( R \) of the unit square consists of a lower and an upper triangular region described by the inequalities \( y^\alpha - x^\alpha > 0 \), \( c_0 - y^\alpha > 0 \) and \( y^\alpha - x^\alpha < 0 \), \( c_0 - y^\alpha < 0 \) respectively. This follows from Eq. (A.3) in which \( x^\gamma \) and \( x^{\alpha \gamma} \) can be replaced by \( y^\alpha \): when \( y^\alpha - x^\alpha > 0 \) then (i) applies and then \( c_0 - y^\alpha \) must be greater than zero for \( \lambda_\alpha \) to be the largest eigenvalue – this accounts for the lower triangle in \( R \); when \( y^\alpha - x^\alpha < 0 \) then (ii) applies and then \( c_0 - y^\alpha \) must be less than zero – this accounts for the upper triangle in \( R \). At the boundaries \( x^\alpha = y^\alpha \) and \( y^\alpha = c_0 \) all the eigenvalues are equal.

We now show that \( \lambda_\alpha \) is positive in \( R \) under the conditions of theorem 3.2.

To do this we only need to consider the four boundaries of \( R \) denoted by \( L_1, L_2, L_3 \) and \( L_4 \). \( L_1, L_2, L_3 \) and \( L_4 \) are subsets of the lines \( y^\alpha = c_0 \), \( x^\alpha = 0 \), \( x^\alpha = 1 \) and \( x^\alpha = y^\alpha \) respectively, contained in the boundary of \( R \). On \( L_1 \), since \( y^\alpha = c_0 = x_1^{(3)} + O(1/N) \), \( \lambda_\alpha \) is positive under A1 and A2 for sufficiently large \( N \) for reasons discussed earlier. For \( L_2 \), it is evident upon substituting \( x^\alpha = 0 \) in (A.1) that \( \lambda_\alpha \) will attain its minimum value at \( y^\alpha = c_0 \) if \( h_{31} - h_{32} - h_{21} < 0 \)
and at \( y^\alpha = 0 \) if \( h_{31} - h_{32} - h_{21} > 0 \). The former is positive for reasons discussed earlier; so is the latter \( (\lambda_\alpha/(N-1)) = h_{32} \) when \( x^\alpha = y^\alpha = 0 \). Similarly on \( L_3 \) one has \( x^\alpha = 1 \); hence \( \lambda_\alpha/(N-1) = h_{32} - h_{12} + (h_{31} - h_{32} + h_{12})y^\alpha \) and this takes its minimum value \( h_{31} \) at the endpoint \( y^\alpha = 1 \) if \( h_{31} - h_{32} + h_{12} < 0 \), or \( u_3/(h_{12} + h_{21}) + O(1/N) \) at the endpoint \( y^\alpha = c_0 \) if \( h_{31} - h_{32} + h_{12} > 0 \). Again under A1, A2 and sufficiently large \( N \) both are positive. Finally, on \( L_4 \), \( y^\alpha = \frac{x^\alpha}{(\equiv x, \text{say})} \), (A.1) reduces to (3.14), and the problem of minimizing \( \lambda_\alpha \) reduces to the one considered below (3.14). Therefore, if \( \lambda_{\min}|_{F_3} > 0 \) (this is one of the conditions in A3), \( \lambda_\alpha \) is guaranteed to be positive on \( L_4 \). This proves that \( \lambda_\alpha \) is positive in \( R \) under the conditions of theorem 3.2.

We now turn to regions I and V. We will show that the projection (to be denoted \( R \)) of \( F_3 \cap (I \cup V) \) onto the \( (x^\alpha, y^\alpha) \) plane is a subset of \( R \). Therefore \( \lambda_\alpha \) is positive in \( F_3 \cap (I \cup V) \) under the conditions of theorem 3.2 (since it is positive in \( R \)). To see this, first consider the projection of I onto the \( (x^\alpha, y^\alpha) \) plane. From the definition of I, the region must be bounded by the lines \( x^\alpha = 0 \) on the left and \( x^\alpha = x^{\gamma_1} \) on the right. Further, since \( y^\alpha \) is the average of all the \( x^\alpha \)’s except \( x^\alpha \), of which \( x^{\gamma_1} \) is the smallest, it follows that \( y^\alpha \) is bounded below by \( x^{\gamma_1} \). The upper boundary of \( y^\alpha \) is the line \( y^\alpha = c_0(1) \) (\( c_0(1) \) was defined above while discussing region III). This constraint comes from the requirement that \( \lambda_\alpha \) be the dominant eigenvalue. It is evident that in I the condition (i) in Eq. (A.3) applies (since \( x^\alpha < x^{\gamma_1} \)) hence \( \lambda_\alpha \) dominance implies \( c_0 \geq x^{\gamma_1} \). Using the definition of \( y^\alpha \) and \( x^{\gamma_1} \), the latter implies that \( y^\alpha \leq c_0(1) \). This proves that the projection of \( F_3 \cap I \) onto the \( (x^\alpha, y^\alpha) \) plane is bounded by the rectangular region given by \( 0 \leq x^\alpha \leq x^{\gamma_1}, x^{\gamma_1} \leq y^\alpha \leq c_0(1) \). We denote this rectangular region by \( R(0) \). We now show that both \( x^{\gamma_1} \) and \( c_0(1) \) are bounded above by \( c_0 \), thereby proving that the rectangle \( R(0) \) is always a subset of the lower triangle in \( R \). Since \( x^{\gamma_1} \) is by definition the average of \( x^{\gamma_1}, \ldots, x^{\gamma_{N-1}} \), all of which are \( \geq x^{\gamma_1} \), it follows from \( c_0 \geq x^{\gamma_{N-1}} \) that \( c_0 \geq x^{\gamma_1} \). Then, from the definition of \( c_0(1) \) it follows that \( c_0 \geq c_0(1) \). Similar arguments hold for \( F_3 \cup V \), showing that its projection on the \( (x^\alpha, y^\alpha) \) plane is always a subset of the upper triangle in \( R \). This completes the proof that \( R \) is contained in \( R \).

It now remains to consider regions II and IV. First consider II. It is convenient to divide II into two subsets:

II.1: \( x^\alpha = x^{\gamma_1} < x^{\gamma_2} \) with \( 0 < x^{\gamma_2} \leq 1 \), and

II.2: \( x^\alpha = x^{\gamma_1} = x^{\gamma_2} \) with \( 0 \leq x^{\gamma_2} < 1 \).

Clearly II = II.1 U II.2. By definition in II, \( y^\alpha \geq x^\alpha \). Again the upper limit of \( y^\alpha \) comes from \( \lambda_\alpha \) dominance. In II, \( \lambda_\alpha \) is always equal to \( \lambda_{\gamma_1} \); for \( \lambda_\alpha \) dominance we need to ensure that this pair remains \( \geq \) the other eigenvalues. In II.1, since \( x^{\gamma_2} - x^{\gamma_1} > 0 \), condition (i) in (A.3) applies, hence \( c_0 - x^{\gamma_2} \geq 0 \Rightarrow y^\alpha \leq c_0(2) \equiv \left(\frac{N-2}{N-1}\right)c_0 + \frac{x^{\gamma_2}}{N-1} \). Therefore the projection of \( F_3 \cap II.1 \) on the \( (x^\alpha, y^\alpha) \) plane is bounded by the rectangle \( R(1) \) given by \( 0 \leq x^\alpha \leq x^{\gamma_2} \) and \( x^{\gamma_2} \leq y^\alpha \leq c_0(2) \). However in the present case (and in this it differs from I) we cannot argue that \( x^{\gamma_2} \) and \( c_0(2) \) must be less than \( c_0 \). This is because while earlier \( x^{\gamma_1} \) was greater than \( x^{\gamma_2} \) by definition, it is no longer necessarily true that \( x^{\gamma_2} \) is greater than \( x^{\gamma_2} \). Thus \( x^{\gamma_2} \) can take values in \( (0,1] \). Nevertheless, \( c_0(2) \) is certainly bounded above by \( c_0(N-1) \) by definition. Hence as \( x^{\gamma_2} \) goes over its entire range, the rectangle
$R^{(1)}$ remains within the lower triangle in $R$ except for a thin strip parallel to the $x^a$ axis of thickness $O(1/N)$ between $y^a = c_0$ and $y^a = c_0^{(N-1)}$. Since in this strip $y^a$ differs from $c_0$ and hence from $x^{(1)}_1$ by $O(1/N)$, $\lambda_\alpha$ remains positive in it under $A_1$, $A_2$ for sufficiently large $N$. This takes care of II.1, leaving us to worry about II.2.

We can repeat the above procedure for II.2: Divide it into two subsets:

II.2.1: $x^a = x^{(1)} = x^{(2)} < x^{(3)}$ with $0 < x^{(3)} < 1$, and

II.2.2: $x^a = x^{(2)} = x^{(3)} = x^{(4)}$ with $0 \leq x^{(4)} \leq 1$.

The argument in the previous para goes through for II.2.1 (we now replace $x^{(3)}$ with $x^{(1)}$ and $c_0^{(1)}$ by $c_0^{(4)} \equiv (N-1) c_0 + x^{(2)}$), leaving us to worry about II.2.2. This process clearly iterates until we are finally left to worry about only the case $x^a = x^{(1)} = \cdots = x^{(N-1)}$. This case has already been dealt with earlier. This proves that $\lambda_\alpha$ is positive in $F^*_2 \cap I$. Similar arguments go through for region IV.

This proves that under $A_1$, $A_2$ and one of the conditions in $A_3$, namely, $1/(N-1) \lambda_{\min} |F_2| > 0$, and for sufficiently large $N$, $\lambda_\alpha$ is positive in the entire region of $F_3$ in which it is the largest eigenvalue. Therefore under the same conditions all points in $F_3$ are unstable with respect to perturbations in which at least one agent moves away from $F_3$. A similar analysis can be performed for $F_1$, $F_2$, which adds the two other conditions in $A_3$. This completes the proof of theorem 3.2.

Note that under the conditions of theorem 3.2, we have proved that every point in $F_k$, $k = 1, 2, 3$ is unstable with respect to perturbations away from $F_k$. This is actually a stronger result than is needed for theorem 3.2 which concerns itself with only trajectories in $F_k$. If there is a certain set of points in $F_k$ which are stable under such perturbations, but with the property that every trajectory that originates from this set always passes through points which are unstable, then we would have a situation in which every trajectory in $F_k$ is unstable though not every point in $F_k$. This remark may prove useful in strengthening the theorem in the following way: In the above proof of $\lambda_\alpha$ being positive in $F^*_3$ we needed condition $A_3$ only in the vicinity of its minimum on the line $L_4$ bounding the region $R$. Everywhere else in the region of $\lambda_\alpha$ dominance only conditions $A_1$, $A_2$ and sufficiently large $N$ were needed. If we could show that all trajectories in this subregion of $F^*_3$ where $A_3$ is needed always flow out of the subregion, the condition $A_3$ would then not be needed in the theorem. In view of theorems 2.6 and 2.6', all that needs to be shown is that none of the equilibrium points in the subfaces of $F_k$ are in this subregion.

**APPENDIX B**

**Proof of Theorem 4.3**

First some notation: At the FDCEP $n$, the payoff to an agent playing the $j^{th}$ pure strategy from the other $N - 1$ agents is

$$P_j = \sum_{k \neq j} a_{jk} n_k + (n_j - 1) a_{jj} = \sum_{k=1}^n a_{jk} n_k - a_{jj} = P_j - a_{jj} \quad (B.1)$$

where $P_j \equiv \sum_{k=1}^n a_{jk} n_k$. If this agent were to suddenly switch to the $i^{th}$ pure strategy ($i \neq j$), all other agents remaining at their respective pure strategies,
then for this agent the payoff would change to \( \sum_{k \neq j} a_{ik} n_k - a_{ij} n_j (n_j - 1) = P_i - a_{ij} \). Thus the increase in payoff for an agent playing the \( j^{th} \) pure strategy at the FDCEP \( \mathbf{n} \) in switching to the \( i^{th} \) pure strategy is

\[
\lambda_{ij} = P_i - P_j - h_{ij}, \quad h_{ij} \equiv a_{ij} - a_{jj}.
\]  

(\(B.2\))

\( \mathbf{n} \) is a strict Nash equilibrium (in the space of pure strategies) if the \( s(s-1) \) conditions

\[
\lambda_{ij} < 0 \quad \forall \quad i \neq j
\]  

(\(B.3\))

are satisfied. From Theorem 3.1, these are identical to the conditions for the asymptotic stability of the FDCEP's associated with \( \mathbf{n} \). It is Eq. (4.1) written in a different notation.

Note that \( P_i - P_j \) figures in both \( \lambda_{ij} \) and \( \lambda_{ji} \). Therefore the \( s(s-1) \) conditions (\(B.3\)) can be written in terms of \( s(s-1)/2 \) "double-sided" inequalities

\[
-h_{ij} < P_i - P_j < h_{ij}.
\]  

(\(B.4\))

Define \( z_i \equiv P_i - P_{i+1} \) for \( i = 1, \ldots, s \), with \( P_{s+1} \equiv P_1 \). Then \( z_i = \sum_{j=1}^{s} c_{ij} n_j \) with

\[
c_{ij} \equiv a_{ij} - a_{i+1,j},
\]  

(\(B.5\))

where it is again understood that \( a_{s+1,j} \equiv a_{ij} \). Now, since all the \( n_j \) are not independent, let us express \( z_i \) in terms of only \( n_1, \ldots, n_{s-1} \) by eliminating \( n_s = n - (n_1 + \cdots + n_{s-1}) \). This gives \( z_i = y_i + c_{is} n \) where

\[
y_i \equiv \sum_{j=1}^{s-1} d_{ij} n_j \quad \text{and} \quad d_{ij} \equiv c_{ij} - c_{is}, \quad i, j = 1, \ldots, s - 1.
\]  

(\(B.6\))

With this notation, consider the subset of \( s-1 \) inequalities obtained by setting \( j = i + 1 \) in (\(B.4\)), with \( i = 1, \ldots, s - 1 \). These involve \( z_i \) and take the form

\[
-h_{i+1,i} - c_{is} n < y_i < h_{i+1,i} - c_{is} n, \quad i = 1, \ldots, s - 1.
\]  

(\(B.7\))

These inequalities mean that for any stable FDCEP \( \mathbf{n} \), the \( y_i \), which, by (\(B.6\)) are linear combinations of \( n_1, \ldots, n_{s-1} \) are constrained to be in an open interval of the real line. While the location of this interval is \( N \) dependent, it follows from (\(B.7\)) that the size of this interval is finite, independent of \( N \), and depends only on the payoff matrix (for \( y_i \) the size of the interval is \( h_{i+1,i} + h_{i,i+1} \)).

If the \( s-1 \) dimensional matrix \( D = (d_{ij}) \) has an inverse, we can invert (\(B.6\)) to express the \( n_j \) in terms of \( y_i \). Then, (\(B.7\)) will get converted into inequalities for \( n_1, \ldots, n_{s-1} \). Since the vector \( \hat{y} = (y_1, \ldots, y_{s-1}) \) in the \( s-1 \) dimensional cartesian space whose axes are the \( y_i \) is constrained by (\(B.7\)) to lie in a (rectangular) parallelepiped, the vector \( \hat{n} = (n_1, \ldots, n_{s-1}) \) in the \( s-1 \) dimensional cartesian space whose axes are the \( n_i \) will also lie in a (in general oblique) parallelepiped which is the image, under \( D^{-1} \), of the rectangular parallelepiped in \( y \)-space defined by (\(B.7\)). Again, while the location of the parallelepiped in \( n_1, \ldots, n_{s-1} \) space will depend upon \( N \), its size, i.e., its extent along any of the coordinate axes, will be independent of \( N \). This is because the matrix \( D^{-1} \), if it exists, depends only on the payoff matrix and not on \( N \). Therefore, if \( D^{-1} \) exists, the differences in \( n_i, i = 1, \ldots, s - 1 \) for all FDCEP are bounded by some function of \( A \) alone, not of \( N \). The same is true for \( n_s \) also since \( \sum_{i=1}^{s} n_i = N \). The existence
of $D^{-1}$ is guaranteed by condition A1 and the following lemma thus completing the proof of the first part of Theorem 4.3.

**Lemma 4.1** \( \det D = \det B \)

**Proof**

\[
D = \begin{pmatrix}
(a_{11} - a_{21}) - (a_{12} - a_{22}) & \cdots & (a_{1,s-1} - a_{2,s-1}) - (a_{1s} - a_{2s}) \\
(a_{21} - a_{31}) - (a_{22} - a_{32}) & \cdots & (a_{2,s-1} - a_{3,s-1}) - (a_{2s} - a_{3s}) \\
\vdots & \vdots & \vdots \\
(a_{s-1,1} - a_{s,1}) - (a_{s-1,s} - a_{s,s}) & \cdots & (a_{s-1,s-1} - a_{s,s-1}) - (a_{s-1,s} - a_{ss})
\end{pmatrix}
\]

\[
B = \begin{pmatrix}
0 & 1 & 1 & \cdots & 1 & 1 \\
-1 & a_{11} & a_{12} & \cdots & a_{1,s-1} & a_{1s} \\
-1 & a_{21} & a_{22} & \cdots & a_{2,s-1} & a_{2s} \\
\vdots & \vdots & \vdots & \vdots & \vdots & \vdots \\
-1 & a_{s-1,1} & a_{s-1,2} & \cdots & a_{s-1,s-1} & a_{s-1,s} \\
-1 & a_{s,1} & a_{s,2} & \cdots & a_{s,s-1} & a_{ss}
\end{pmatrix}
\]

(B.8)

One can manipulate the determinant of $B$ by subtracting the third row from the second, the fourth row from the third, \ldots, and the \( s + 1 \)th row from the \( s \)th. As a result \( \det B \) is equal to

\[
\begin{vmatrix}
0 & 1 & 1 & \cdots & 1 & 1 \\
0 & a_{11} - a_{21} & a_{12} - a_{22} & \cdots & a_{1,s-1} - a_{2,s-1} & a_{1s} - a_{2s} \\
0 & a_{21} - a_{31} & a_{22} - a_{32} & \cdots & a_{2,s-1} - a_{3,s-1} & a_{2s} - a_{3s} \\
\vdots & \vdots & \vdots & \vdots & \vdots & \vdots \\
0 & a_{s-1,1} - a_{s,1} & a_{s-1,2} - a_{s,2} & \cdots & a_{s-1,s-1} - a_{s,s-1} & a_{s-1,s} - a_{ss} \\
-1 & a_{s,1} & a_{s,2} & \cdots & a_{s,s-1} & a_{ss}
\end{vmatrix}
= (-1)^{s+1} \chi
\]

One can now subtract the last column from all other columns without changing the determinant. The result is

\[
\det B = (-1)^{s+1} \chi
\]

\[
\begin{vmatrix}
0 & 1 & 1 & \cdots & 1 & 1 \\
0 & a_{11} - a_{21} & a_{12} - a_{22} & \cdots & a_{1,s-1} - a_{2,s-1} & a_{1s} - a_{2s} \\
0 & a_{21} - a_{31} & a_{22} - a_{32} & \cdots & a_{2,s-1} - a_{3,s-1} & a_{2s} - a_{3s} \\
\vdots & \vdots & \vdots & \vdots & \vdots & \vdots \\
0 & a_{s-1,1} - a_{s,1} & a_{s-1,2} - a_{s,2} & \cdots & a_{s-1,s-1} - a_{s,s-1} & a_{s-1,s} - a_{ss} \\
(a_{s-1,1} - a_{s,1}) - (a_{s-1,s} - a_{ss}) & \cdots & (a_{s-1,s-1} - a_{s,s-1}) - (a_{s-1,s} - a_{ss}) & a_{s-1,s} - a_{ss}
\end{vmatrix}
= (-1)^{s+1}(-1)^{s-1} \det D = \det D.
\]

To prove the second part of Theorem 4.3, divide all sides of (B.4) by $N$ and take the limit $N \to \infty$. This yields $\lim_{N \to \infty} \left( \frac{x_i}{N} - \frac{x_i}{N} \right) = 0$. Defining $x'_i \equiv \lim_{N \to \infty}(n_i/N)$ along an appropriate subsequence independent of $i$, this is equivalent to the statement that $\sum_{k=1}^N a_{ik}x_k$ is independent of $i$, which implies that $x'$ is the same as $x$, the IEP of PRD (see remarks following (2.2)). \( \Box \)

We now remark that the existence of a finite volume parallelepiped is a consequence of the exclusion of the $\beta = \alpha$ term in (1.2), or the fact that an agent $\alpha$ only plays against other agents and not with herself. To see this, note that if the $\beta = \alpha$ term were not excluded in the r.h.s. of (1.2), then in (4.1) $n_i - 1$
would be replaced by $n_k$. Consequently in (B.2) the eigenvalues will be given by $\lambda_{ij} = P_i - P_j$, and the double sided inequality (B.4) would be replaced by $0 < P_i - P_j < 0$ which has no solution. That is, there could be no stable FDCEP, or no specialization with diversification in the community.
